One sentence summary: The work provides insights on optimal growth conditions of microaerophilic iron(II)-oxidizing bacteria under which they can compete with fast chemical iron(II) oxidation by oxygen.

Editor: Tillmann Lueders

**ABSTRACT**

The classical approach for the cultivation of neutrophilic microaerophilic Fe(II)-oxidizing bacteria is agar-based gradient tubes where these bacteria find optimal growth conditions in opposing gradients of oxygen (O₂) and dissolved Fe(II) (Fe²⁺). The goals of this study were to quantify the temporal development of O₂ and Fe²⁺ concentrations over time, to compare abiotic and microbially inoculated tubes and to test the suitability of different Fe(II)-sources for the cultivation of freshwater and marine microaerophilic Fe(II)-oxidizers. O₂ and Fe²⁺ gradients were monitored on a high spatial resolution as a function of time applying amperometric and voltammetric microsensors. Fe(II)-oxidizers could be cultivated well with FeS and zero-valent iron powder as Fe(II)-source, but FeCO₃ and FeCl₂ are extremely sensitive for this application. Fe(III) minerals accumulated in inoculated tubes within the first days in regions with an O₂ concentration of 20–40 μM were confirmed to be related to bacterial growth. Microbial Fe(II) oxidation could compete only for the first days with the abiotic reaction after which heterogeneous Fe(II) oxidation, catalyzed by Fe(III) minerals, dominated. Our results imply that transfer of cultures to fresh tubes within 48–72 h is crucial to provide optimal growth conditions for microaerophilic Fe(II)-oxidizers, particularly for the isolation of new strains.

Keywords: microaerophilic iron(II) oxidation; iron(II)-oxidizing bacteria; iron cycling; gradient tubes

**INTRODUCTION**

Iron is one of the most dominant chemical elements in the continental crust (Taylor 1964), and it is an important component of several geological, mineralogical, environmental and microbial processes. As an essential micronutrient, iron is integrated in many cellular compounds and has high relevance in modern and ancient, as well as in extraterrestrial environments. In the environment, iron is often involved iniotic and abiotic redox processes (Melton et al. 2014) and mainly occurs in two redox states: as oxidized ferric iron (Fe(III)) or as reduced ferrous iron (Fe(II)). At circumneutral pH, Fe(III) is poorly soluble (CORNELL and SCHWERTMANN 2003) and normally occurs as solid Fe(III)
minerals; soluble Fe(III) (Fe^{3+}), either, freely dissolved, or more often complexed with organic molecules, is only present at very low concentration in the range of 10^{-6}−10^{-9} M (Taillefert Bono and Luther 2000; Kappler and Straub 2005). In contrast, Fe(II) is more soluble and therefore more bioavailable for organisms (Melton et al. 2014); however, at neutral pH, it is rapidly chemically oxidized in the presence of oxygen (O_2) (Davison and Seed 1983; Stumm and Morgan 1996). During homogenous abiotic Fe(II) oxidation, dissolved Fe(II) (Fe^{2+}) is oxidized by dissolved O_2 and other intermediate oxygen species that are formed during the stepwise reduction of O_2 (Melton et al. 2014). The formed Fe^{3+} will instantaneously react with water and precipitate as the Fe(III) oxyhydroxide mineral with a rusty-orange color (Emerson and Weiss 2004). These mineral precipitates serve as catalyst for further chemical Fe(II) oxidation, an autocatalysis reaction also called heterogeneous Fe(II) oxidation (Tamura Goto and Nagayama 1976; Rentz et al. 2007). Both, heterogeneous and homogeneous Fe(II) oxidation run in parallel; however, heterogeneous Fe(II) oxidation is faster so that homogeneous Fe(II) oxidation becomes of minor importance (Stumm and Sulzberger 1992; Park and Dempsey 2005) once sufficient iron oxyhydroxides are formed. Besides the chemical redox transformations, microbes contribute to a large extent to the cycling between the redox states of iron (Weber Achenbach and Coates 2006; Konhauser Kappler and Roden 2011). Fe(III)-reducing bacteria can reduce Fe(III) to Fe(II) under anoxic conditions using electron donors such as hydrogen (H_2), acetate or lactate (Kashefi and Lovley 2000; Lovley et al. 2011). On the other hand, Fe(II) can be oxidized enzymatically by photoautotrophic Fe(II)-oxidizers using light energy with bicarbonate as electron acceptor and carbon source (Widdel et al. 1993; Hegler et al. 2008). Other microorganisms couple Fe(II) oxidation to nitrate (NO_3^-) reduction under anoxic conditions (Straub et al. 1996). However, most nitrate-reducing Fe(II)-oxidizers need an additional organic co-substrate to continually oxidize Fe(II) to Fe(III) (Straub et al. 1996; Klueglein et al. 2014). Microaerophilic Fe(II)-oxidizers can oxidize Fe(II) as a sole electron donor using O_2 as electron acceptor for lithotrophic growth (Emerson and Moyer 1997). Bacteria that are capable of aerobic neutrophilic Fe(II) oxidation have to oxidize Fe(II) as a sole electron donor using O_2 as electron acceptor for growth in laboratory setups difficult. The traditional technique used is the cultivation of microaerophilic Fe(II)-oxidizers in agar-stabilized gradient tubes with opposing gradients of Fe^{2+} and O_2 (Emerson and Moyer 1997; Sobolev and Roden 2001; Emerson and Moyer 2002; Neubauer Emerson and Megonigal 2002; Edwards et al. 2003; Weiss et al. 2003; Emerson and Floyd 2005; Weiss et al. 2007; Druschel et al. 2008; Swanner Nell and Templeton 2011; Lin et al. 2012; MacDonald et al. 2014; Lauffer et al. 2016). By analyzing Fe^{2+} and O_2 concentrations at high spatial resolution as well as the development of the competitive pressure between biotic and abiotic Fe(II) oxidation, conclusions about optimal substrate demands and habitat limitations by kinetic constraints can be drawn. So far, the geochemical conditions in gradient tubes were examined only in a few studies (Druschel et al. 2008; Swanner Nell and Templeton 2011). However, spatially highly resolved measurements as a function of time are missing. These measurements are important to determine the optimal time point for transfer of cultures, which is a critical parameter for isolation and continuous cultivation. Also, different Fe(II)-sources (Emerson and Moyer 1997; Druschel et al. 2008; Swanner Nell and Templeton 2011; Emerson et al. 2013; MacDonald et al. 2014) for gradient tubes are mentioned in the literature, but they have not been compared systematically in terms of suitability for growth of microaerophilic Fe(II)-oxidizers.

Therefore, the goals of this study were (i) to test and compare iron sulfide (FeS), iron carbonate (FeCO_3), zero-valent iron powder (ZVI) and iron chloride (FeCl_3) as Fe(II)-sources for the suitability of growth of selected freshwater and marine neutrophilic microaerophilic Fe(II)-oxidizing bacteria, (ii) to quantify O_2 and Fe^{2+} profiles as a function of time at high spatial resolution using amperometric and voltammetric microsensors and (iii) to identify exact physico-chemical conditions for optimal growth to give recommendations and improve isolation and cultivation of new microaerophilic Fe(II)-oxidizers.

**MATERIAL AND METHODS**

**Cultivation of bacteria**

Gradient tube preparation was based on Emerson and Floyd (2005). Opposing gradients of Fe^{2+} and O_2 in screw-cap vials (8 ml, 61 × 16.6 mm) were established by adding 750 μl of a 1% (wt/vol) high-melt agarose containing a plug (height approx. 5 mm) of FeS, FeCO_3, FeCl_3 or by spreading ZVI (200 mesh; metal basis; Alfa Aesar, Ward Hill, MA) at the bottom of the glass vial, in this latter case, no high melt agarose was used. FeS was synthesized in a modified way as described by Kucera and Wolfe (1957) by reacting equimolar amounts of sulfide with Fe(II) using Na_2S × 9H_2O and FeSO_4 × 7H_2O. After being separately dissolved in 80°C anoxic deionized water (Milli-Q Integral System, Merck Millipore), the FeSO_4 solution was quickly added to the Na_2S solution resulting in instantaneous precipitation of FeS. This precipitate was allowed to settle overnight. The supernatant of the settled FeS was washed two to three times with each time 2 L warm anoxic distilled water (−80°C) until the water above the FeS looked clear and had a pH around neutrality.

FeCO_3 was synthesized by reacting equimolar amounts of Fe(II) chloride with sodium bicarbonate. The Fe(II)-source was overlaid by 3.75 ml of a 0.15% (wt/vol) low-melt agarose containing semisolid mineral salt medium of either modified Wolfe’s mineral medium (MWWM) or artificial seawater medium (ASW), including 1 ml L^{-1} of 7-vitamin (Pfennig 1978), SL10- (Tschech and Pfennig 1984) and selenite-tungstate (Tschech and Pfennig 1984) solutions. The media were buffered with 10 mM bicarbonate and the pH was adjusted to 6.5 by stepwise addition of 1 M HCl and constantly checking the pH with a pH electrode. MWMM contained of the following salts per liter: 0.1 g NH_4Cl, 0.2 g MgSO_4 × 7 H_2O, 0.1 g CaCl_2 × 2 H_2O and 0.05 g K_2HPO_4. Per liter, ASW was composed of 17.3 g NaCl, 8.6 g MgCl_2 × 6 H_2O, 0.025 g MgO_2 × 7 H_2O, 0.996 g CaCl_2 × 2 H_2O, 0.034 g KCl, 0.059 g KBr, 0.25 g NH_4Cl and 0.05 g K_2HPO_4. For comparison, a batch of FeCO_3 was prepared following the protocol of Hallbeck, Stähl and Pedersen (1993) using Fe(NH_4)SO_4 and Na_2CO_3 instead of FeCl_3 and NaHCO_3 for synthesis. The tubes were prepared anoxically and opened the first time during inoculation with bacteria one day after preparation, leading to an air-filled headspace.
The tubes were inoculated under sterile conditions with 50 μL, which was a tenfold diluted sample from another gradient tube and incubated at 20°C in the dark. An Fe(II)-oxidizing culture dominated by Betaproteobacteria (belonging to Gallionella sp.) and with minor traces of Alphaproteobacteria (belonging to Azorhizobium sp.) enriched from a freshwater sediment (Lake Constance, N 47° 41’ 42.63”; E 9° 11’ 40.29”., Germany) was selected and a culture of a marine Fe(II)-oxidizer, belonging to the Zetaproteobacteria (98% homolog to Mariprofundus sp. M34), isolated from sediment from Aarhus Bay (N 56° 16.811’; E 010° 28.056’; Baltic Sea, Denmark) was used as marine Fe(II)-oxidizer representative (Lauf et al. 2016). The negative control was treated in a similar way without inoculation. Growth of bacteria was defined as positive if brownish accumulations that spread out from the inoculum could be visually observed and clear differentiation from the negative control could be done (Emerson and Floyd 2005). This will henceforth be called Fe(III) mineral accumulations.

**Cell counts**

Bacterial cells in the top layers of freshly prepared MWMM with FeS gradient tubes were counted by fluorescent microscopy in triplicates at each time point to demonstrate bacterial growth. For cell counts, the top layer of the gradient tubes was centrifuged and the cell-mineral pellet was resuspended in 1.5 ml of 10 mM bicarbonate buffer. Parformaldehyde at a final concentration of 2% was added and the samples were stored at 4°C until analysis. One ml of this suspension was added to 9 ml of oxalate solution (28 g L⁻¹ ammonium oxalate and 15 g L⁻¹ oxalic acid) to dissolve the Fe(III) minerals and further tenfold diluted in oxalate solution. Ten ml were then filtered onto a white GVWP filter (Millipore, 0.22 μm) and 1 μg ml⁻¹ DAPI stain was used to stain the cells. Cells were counted using a Leica DMS500B fluorescent microscope using the A4 filter.

**Geochemical measurements**

Geochemical measurements were always performed in the same gradient tubes using microsensors at 20°C. For each setup, two gradient tubes were inoculated and two additional gradient tubes were prepared as negative control. Concentration profiles were performed only once in every gradient tube at each time point to disturb the system as little as possible. O₂ concentration depth profiles were measured with a 100 μm tip diameter amperometric Clark-type O₂ microelectrode (Unisense, Aarhus, Denmark) as described by Revsbech (1989). A two-point calibration was done in air-saturated and in anoxic water. Vertical O₂ profiles in gradient tubes were recorded in triplicates in depth intervals of 0.5 mm using a motorized micromanipulator (Unisense) and used for the calculation of O₂ consumption rates using the program PROFILE 1.0 (Berg Risgaard-Petersen and Rysgaard 1998). The O₂ concentration measured at the top of the top layer (depth 0 mm) was chosen as first boundary condition, an O₂ flux at the bottom of the tube (21 mm) of 0 μmol dm⁻² s⁻¹ was set as second boundary condition and an O₂ diffusion coefficient of 2.4·10⁻⁹ m² s⁻¹ (McMillan and Wang 1990) was used.

All microsensor data for measurements in gradient tubes were plotted as follows: depth 0 mm refers to the atmosphere/top layer (agar) interface, and the surface of the Fe(II)-source is located at approx. 21 mm. The time between the single measurement time points are 1 (t₀ – t₁) and 3 days (t₃ – t₄).

Fe²⁺ concentration depth profiles were determined by voltammetry using a DLK-100A potentiostat (Analytical Instrument Systems, Flemington, NJ) with a standard three-electrode system. The working electrode, a glass-encased 100 μm gold amalgam (Au/Hg) electrode, was constructed as described by Brendel and Luther (1995). The reference electrode was a solid-state Ag wire coated in Ag/AgCl, a Pt wire was used as counter electrode. Working and reference electrode were re-plated before every daily measurement. Fe²⁺ calibrations were done using Mn²⁺ standards with subsequent conversions to Fe²⁺ concentrations using the pilot ion method (Brendel and Luther 1995; Slowey and Marvin-DiPasquale 2012). A conversion factor from Mn²⁺ to Fe²⁺, called pilot ion factor was determined to be 1.3. For this, a proper calibration for Fe²⁺ and Mn²⁺ was performed in an anoxic glovebag to prevent any Fe²⁺ oxidation. The slopes of the calibrations were then divided by each other (Mn²⁺/Fe²⁺). The determined conversion factor was later used for any calibrations that have been performed with Mn²⁺ prior to measurements. Cyclic voltammetry was performed for the detection of Mn²⁺ and Fe²⁺ at 1000 mV s⁻¹ between −0.1 and −2.0 V (freshwater) or −1.8 V (seawater) vs Ag/AgCl. An initial conditioning step of applying −0.05 V for 5 s followed by holding −0.9 V for 10 s were set to remove previously deposited species (Brendel and Luther 1995). After the conditioning steps, the electrode equilibrated for 5 s before scan potentials were applied. 10 scans were run at each measurement point, the final 3 voltammograms were integrated using VOLTINT program for Matlab® (Bristow and Taillefert 2008). Data were recorded in 4 mm depth intervals using a manual micromanipulator (Unisense, Aarhus, Denmark). Fe²⁺ consumption rates were not calculated because the low amount of data points led to statistically invalid results.

**Energetic and kinetic calculations**

The overall reaction of homogeneous oxidation of Fe²⁺ by dissolved O₂ to Fe³⁺ and further precipitation as Fe(III) hydroxide can be summarized as (Roden et al. 2004)

$$Fe^{2+} + 0.25 O_2 + 2.5 H_2O \rightarrow Fe(OH)_3 + 2 H^+ \quad (1)$$

Values of Gibbs free energy ΔG of this reaction in different depths and time points were calculated according to

$$\Delta G = \Delta G_0 + R \cdot T \cdot \ln Q \quad (2)$$

with ΔG₀ as the standard Gibbs free energy of the reaction (−109 kJ mol⁻¹ (Roden et al. 2004)), R as the ideal gas constant, T as the temperature in Kelvin and Q as the activity product of the reaction.

Considering homogeneous Fe²⁺ oxidation only, the kinetic rate law for neutral solutions then is

$$- \frac{d[Fe^{2+}]}{dt} = k \cdot [Fe^{2+}] \quad (3)$$

with $k = k_0 \cdot [O_2] \cdot [OH^-]^2$ and the universal rate constant for homogeneous Fe²⁺ oxidation by O₂ kₐ being 2.3·10⁻¹⁴ mol⁻¹ L⁻³ s⁻¹ at 25°C (Tamura Goto and Nagayama 1976). The total general rate equation of Fe²⁺ oxidation considering both, homogenous and heterogeneous oxidation, was found to be (Tamura Goto and Nagayama 1976)

$$- \frac{d[Fe^{2+}]}{dt} = (k + k' \cdot [Fe(III)]) \cdot [Fe^{2+}] \quad (4)$$
Heterogeneous Fe$^{2+}$ oxidation is accelerated by Fe(III) minerals (Tamura Kawamura and Hagayama 1980). The amount of Fe(III) hydroxide precipitated is equal to the amount of oxidized Fe$^{2+}$ (Tamura Goto and Nagayama 1976); therefore, $[\text{Fe(III)}]$ in the gradient tube top layer at any time can be calculated by

$$[\text{Fe(III)}] = [\text{Fe}^{2+}]_{t_0} - [\text{Fe}^{2+}]$$

The rate law of heterogeneous Fe$^{2+}$ oxidation can be described as

$$-\frac{d[\text{Fe}^{2+}]_{\text{hrt}}}{dt} = k' \cdot [\text{Fe(III)}] \cdot [\text{Fe}^{2+}]$$

with $k' = \frac{k_{s,0} \cdot [O_2]}{[\text{Fe}^{2+}]^{1.2}}$ and the specific rate constant for the heterogeneous reaction $k_{s,0}$ being 73 mol L$^{-1}$ s$^{-1}$ (Tamura Goto and Nagayama 1976) and the dimensionless adsorption constant of ferrous iron on ferric hydroxide $K$ being 10$^{-4.85}$ (Sung and Morgan 1980). Additionally, half-life for Fe$^{2+}$ oxidation in the gradient tubes was calculated by equations (7) and (8) for homogenous or heterogeneous Fe$^{2+}$ oxidation, respectively

$$t_{1/2, \text{hom}} = \frac{\ln (2)}{k}$$

$$t_{1/2, \text{hrt}} = \frac{\ln (2)}{k' \cdot [\text{Fe(III)}]}$$

The energetic and kinetic calculations were exemplarily done for gradient tubes containing MWMM and FeS as Fe(II)-source.

RESULTS

Comparison of different Fe(II)-sources for suitability of growth of microaerophilic Fe(II)-oxidizers

We found that both FeS and ZVI are suitable Fe(II)-sources for the cultivation of freshwater and marine microaerophilic Fe(II)-oxidizers in opposed Fe$^{2+}$-O$_2$ gradient tubes using agar as a stabilizing agent. In these gradient tubes, a diffuse orange-brownish smear was observed 1 day after inoculation in the center of the top layer in inoculated as well as in negative control tubes (both MWMM and ASW medium) (Fig. 1). First distinct Fe(III) mineral accumulations appeared 2–3 days (freshwater Fe(II)-oxidizers) and 5–6 days after inoculation (marine Fe(II)-oxidizers), respectively. Cell counts in freshly prepared gradient tubes containing MWMM and FeS clearly demonstrated an increasing cell number and thus microbial growth in the area of the distinct Fe(III) mineral accumulations (Fig. 2). Depending on the identity of Fe(II)-source and the identity of the inoculated bacteria, the shape and the height of the formed distinct Fe(III) mineral accumulation (often described in the literature as band formations) can be different (Fig. 3), including flat plane (Fig. 3A and D), funnel-like (Fig. 3C and E), curved plane (Fig. 3B) and cloud structures (Fig. 3F).

In addition to these setups, ZVI was stabilized in a 1% high melt agarose bottom layer so the ZVI was not in direct contact with the low melt agarose where the bacteria grew. In this case, accumulations of Fe(III) minerals were observed only in minor amounts at the surface of the bottom layer (image not shown). Similar to the gradient tubes that contained FeCO$_3$ (mineral prepared following two different protocols) and FeCl$_2$ as Fe(II)-source, this setup did not reveal significant growth of Fe(II)-oxidizing bacteria (data not shown). The Fe(II)-sources in
gradient tubes that contained FeCO₃ as bottom layer got oxidized within a day after inoculation (Fig. 1) and therefore did not show any Fe²⁺ gradients across the top layer. A similar absence of Fe²⁺ gradients was obtained for tubes that had been kept anoxically for 2 days in order to provide optimal conditions for the establishment of a pronounced Fe²⁺ gradient across the top layer. Spectrophotometric quantification of dissolved Fe(II) (ferrozine assay) revealed only low concentrations of Fe²⁺ compared to water saturation (approximately 50 μM, data not shown). The mineralogical identity of FeCO₃ was verified by Mössbauer spectroscopy analysis (data not shown). FeCl₂ gradient tubes were set up with different concentrations in the bottom layer (1 mM, 500 μM, 200 μM). In none of these tubes were Fe(III) mineral accumulations observed. A summary of the observations is listed in Table 1.

Geochemical depth profiles

Exemplary O₂ concentration depth profiles from gradient tubes inoculated with an enrichment of freshwater Fe(II)-oxidizers from Lake Constance (Fig. 3A and B) or with a marine isolate from Aarhus Bay (Fig. 3C) are shown in Fig. 4. The O₂ concentration decreased in all tubes towards the bottom of the tube. No O₂ reached the bottom of tubes during the day of inoculation (t₀) (Fig. 4). O₂ concentrations increased over time over the whole depth until stabilization beginning at t₂ (day 2; ZVI tubes) or t₃ (day 3; FeS tubes). At t₂, the first distinct Fe(III) mineral accumulations were formed in the inoculated FeS freshwater tubes at a depth of around 16 mm, corresponding to an O₂ concentration of approx. 20 μM. No O₂ was detected at t₂ below these accumulations, which were close to the Fe(II)-source at the bottom of the tube (Fig. 4A). In the ZVI freshwater tubes, Fe(III) minerals also accumulated at t₃ at a depth of approximately 18 mm. The temporal shifts of the O₂ distribution throughout the tubes containing ASW (Fig. 4C and D) mirror the trend that was observed in tubes containing MWMM (Fig. 4A and B). In all tubes the spatial O₂ distribution profiles shift from a concave to a linear shape over time, which reflects the shift of dominant O₂ consumption zones from top to bottom of the tubes (Fig. 5). O₂ concentrations were slightly lower in ASW setups. During the entire experiment, significant differences in O₂ concentrations between negative control tubes and inoculated tubes were observed only during short time frames, e.g. at t₂ in freshwater FeS tubes (Fig. 4A).

Emerson and Moyer (1997) noted a depletion of O₂ in the headspace of inoculated gradient tubes. Renewing the headspace by opening the tube again led to the formation of a second growth band consisting of Fe(III) mineral accumulations below the already grown first band. In the present study, the tubes were opened daily to measure the O₂ concentrations, which led to a frequent regeneration of the headspace in the tubes. To ensure that the renewed headspace had no influence on the O₂ concentrations in the top layer, additional tubes were prepared that were all inoculated at the same time and just opened once again when they were measured. They did not have significantly lower O₂ concentrations than the tubes that were opened daily for measurements (data not shown). This also shows that no significant additional O₂ entered the top layer by the microelectrode insertion or removal.

O₂ consumption rates for gradient tubes containing MWMM and FeS are shown in Fig. 5. Consumption rates in the other gradient tubes that have been used for measurements were in a similar order of magnitude (0–12 nmol L⁻¹ s⁻¹). Over time, the O₂ consumption shifted in all gradient tubes down towards the bottom of the tube. After 3–4 days, O₂ was only consumed below 15 mm in the top layer with O₂ consumption rates of below 10 nmol L⁻¹ s⁻¹. No significant differences in O₂ consumption were observed between negative control tubes and inoculated tubes.

Exemplary Fe²⁺ concentration depth profiles are shown in Fig. 6. The highest Fe²⁺ concentrations were measured at the bottom of all tubes with decreasing concentrations upwards. At t₀, Fe²⁺ concentrations of about 2.5 μM were measured directly above the bottom layer in freshwater FeS tubes (Fig. 6A). Fe(III) mineral accumulations were visually observed starting at t₂. First mineral accumulation appeared in the center of the tube (right at the inoculation funnel) and spread in all directions with Fe²⁺ concentrations of approximately 300–400 μM. From t₀ to t₃, an additional peak in the voltammograms at E₁/₂ = −1.1 V vs. Ag/AgCl in depths below 12 mm depth was detected in the cathodic wave that was identified as FeS⁰ signal. These data could not be quantified due to a lack of standards for FeS⁰ (Davison Buffle and DeVitre 1998; Luther et al. 2003; Ciglenecki...
et al. 2014). This leads to some underestimation of total dissolved Fe$^{2+}$ concentrations in these tubes. Similar to the FeS tubes, Fe(III) mineral accumulations in freshwater ZVI tubes were observed from $t_2$ in regions with about 300–400 $\mu$M Fe$^{2+}$. In gradient tubes containing ASW and a FeS bottom layer, a small extent of Fe(III) mineral accumulations was observed at $t_6$ directly at the bottom of the tubes, where Fe$^{2+}$ concentrations of approximately 100–200 $\mu$M were measured. No significant differences in measured Fe$^{3+}$ concentrations between negative control tubes and inoculated tubes were measured. In gradient tubes with ASW and ZVI as Fe(II)-source, first Fe(III) mineral accumulations appeared at $t_1$ in regions with about 500–700 $\mu$M Fe$^{2+}$. In general, Fe$^{2+}$ concentrations decreased over the time of the experiment. Higher Fe$^{3+}$ concentrations were generally measured in gradient tubes using FeS as Fe(II)-source. The gradients in negative control tubes and inoculated tubes were with some exceptions very similar (Fig. 6).

Calculations using Gibbs free energy show potentially higher energy for the metabolism of Fe(II)-oxidizing bacteria during Fe(II) oxidation at greater depths within the top layers of the gradient tubes (Fig. 7A). However, the amount of energy that can be obtained decreases with time. Kinetic calculations reveal higher rates of homogeneous Fe(II) oxidation near the top layer headspace interface (depth 0 mm) due to higher O$_2$ concentrations and consequently a shorter half-life of Fe$^{2+}$ in solution (Fig. 7B and C). A comparison between homogeneous and heterogeneous Fe(II) oxidation rates in 16 mm depth of the top layer exhibit a rapid overtaking of the heterogeneous oxidation leading to a dramatic decrease of Fe$^{3+}$ half-life times from $t_1$ in this depth (Fig. 7D).

**DISCUSSION**

**Suitability of different Fe(II)-sources for cultivation in gradient tubes**

In this study, we have compared the suitability of the different Fe(II)-sources FeS, FeCO$_3$, ZVI and FeCl$_2$ for the cultivation of freshwater and marine microaerophilic Fe(II)-oxidizers in agar-stabilized gradient tubes. Although successful growth has been
reported in the literature for all Fe(II)-sources (Emerson and Moyer 1997; Sobolev and Roden 2001; Neubauer Emerson and Megenical 2002; Edwards et al. 2003; Weiss et al. 2007; Druschel et al. 2008; McBeth et al. 2011; Swanner Nell and Templeton 2011; Kato et al. 2012; Kato et al. 2013; MacDonald et al. 2014; Lauer et al. 2016), in the present study we have only observed the formation of orange Fe(III) (oxyhydr)oxide minerals using FeS and ZVI. FeCl$_2$ and FeCO$_3$ tubes, no diffusion of Fe$^{2+}$ was observed into the top layer, leading to the lack of the orange band and no growth of microaerophilic Fe(II)-oxidizers. We could show that FeCO$_3$ and FeCl$_2$ are highly sensitive in handling with respect to stability and oxygen sensitivity. Minor variations in handling and preparation cause failure of the method. Rapid oxidation directly at the Fe(II) plug confirmed that chemical oxidation by O$_2$ prevents the establishment of an Fe$^{2+}$ gradient throughout these FeCl$_2$ and FeCO$_3$ tubes. These observations are in agreement with geochemical properties of these Fe(II) phases. The FeCO$_3$ solubility at room temperature and low ionic strength has been shown to be 3.72 × 10$^{-11}$ to 9.33 × 10$^{-12}$ mol$^2$ L$^{-2}$ (Sun Nešić and Woollam 2009). The fast rate of chemical Fe$^{2+}$ oxidation, combined with the low solubility of FeCO$_3$ and low diffusion of Fe$^{2+}$ (0.719 × 10$^{-9}$ m$^2$ s$^{-1}$ (Lide 2008)) leads to rapid depletion of Fe$^{2+}$ in the top layer of gradient tubes. The solubility product of FeS has been determined to be significantly higher, in the range of 10$^{-2.95}$ (amorphous FeS) (Davison 1991) to 10$^{-3.5}$ (Rickard and Luther 2007). Increasing solubility of the Fe(II) minerals enhances the diffusion of Fe$^{2+}$ into the top layer. However, an accurate estimation of released Fe$^{2+}$ to the top layer from the FeS bottom plug is impossible, as the mineral ageing of FeS (including Ostwald ripening and mineral transformation) significantly affects FeS solubility.

Few studies reported on the successful growth of microaerophilic Fe(II)-oxidizers in gradient tubes using FeCO$_3$ as Fe(II)-source (Emerson and Moyer 1997; Swanner Nell and Templeton 2011; Emerson et al. 2013; MacDonald et al. 2014; Field et al. 2016; Chiu et al. 2017). In these studies, FeCO$_3$ was synthesized following the protocol of Hallbeck, Stähl and Pedersen (1993). Following this procedure, we revealed similar results compared to the use of FeCO$_3$ that was prepared after our lab protocol. This confirms the high sensitivity of this mineral for the application as Fe(II)-source for gradient tubes, using Fe(NH$_4$)SO$_4$ and Na$_2$CO$_3$ instead of FeCl$_2$ and NaHCO$_3$ for synthesis. In these studies, it was also noted that only fresh FeCO$_3$ could be used, since the FeCO$_3$ lost potency to release Fe$^{2+}$ within one week.

FeCl$_2$ concentrations used in this study (1 mM, 500 μM and 200 μM) were low compared to those used by Sobolev and Roden (50 mM) (2001). They used concentrations that were much too high (50 mM) compared to concentrations observed in natural systems in a 250 ml beaker overlaid by a 125 ml top layer to sustain an environmentally relevant Fe$^{2+}$ flux over the course of the experiment. As the glass vials used in this study only have a small volume of 8 ml, lower Fe(II) concentrations were chosen. Higher FeCl$_2$ concentrations (up to 10 mM) as iron source in the bottom layer were tested for the growth of microaerophilic Fe(II)-oxidizers (data not shown); however, no distinct Fe(III) mineral accumulations (that are linked to biotic Fe(II) oxidation) were observed in any of them. Only a fast color change to orange could be seen in the top layer, which is related to fast chemical oxidation.

A comparison between FeS and ZVI tubes showed that both Fe(II)-sources worked equally well for cultivation of both freshwater and marine microaerophilic Fe(II)-oxidizers. The method to use ZVI as Fe(II)-source in gradient tubes was used for marine strains as the corrosion rates are expected to be higher due to higher ionic strength. However, few studies using ZVI had success with freshwater strains ((Kato et al. 2012), this study). In ZVI gradient tubes, distinct Fe(III) mineral accumulations indicating growth of Fe(II)-oxidizers occurred sometimes slightly earlier than in FeS tubes. Finally, the differences in the gradient tubes are dependent on the physico-chemical parameters of the Fe(II)-source and the gradient tube medium. A higher solubility of the Fe(II)-source generally leads to steeper diffusion gradients and consequently to faster diffusion of Fe$^{3+}$ into the top layer.

### Table 1. Summary of observations in opposed gradient tubes with different Fe(II)-sources.

Figure 4. Selected O$_2$ concentration depth profiles in gradient tubes inoculated with an enrichment of freshwater microaerophilic Fe(II)-oxidizers from Lake Constance, Germany (A,B) or with an isolate of a marine Fe(II)-oxidizer from Aarhus Bay, Denmark (C,D). Open symbols and dashed lines represent negative control tubes, closed symbols and solid lines inoculated tubes. Error bars are not shown as the mean coefficient of variation of all profiles is below 3%. The colors display the different times of measurements starting the day of inoculation ($t_0$). Depth 0 mm shows the headspace-top layer interface; the Fe(II)-source starts in a depth of about 21 mm. The arrow indicates the approximate level where the growth band formed in inoculated tubes. (A) Gradient tubes with MWMM and FeS bottom layer; (B) Gradient tubes with MWMM and ZVI powder at the bottom; (C) Gradient tubes with ASW and FeS bottom layer; (D) Gradient tubes with ASW and ZVI powder at the bottom. ($t_1$ = day 1, $t_2$ = day 2, $t_3$ = day 3 and $t_6$ = day 6 after inoculation).
Figure 5. O₂ consumption profiles for gradient tubes for negative control tubes (dashed lines) and inoculated tubes (solid lines) for different measurement time points (t₀ = day of inoculation, t₁ = day 1, t₂ = day 2, t₃ = day 3 and t₆ = day 6 after inoculation) in gradient tubes containing MWMM and a FeS bottom layer that starts at a depth of approx. 21 mm. Error bars show the minimum and maximum of the duplicate O₂ concentration measurements. Data were obtained using PROFILE 1.0. Oxygen consumption rates in inoculated tubes in the first 3 mm at t₆ are not shown due to falsified data resulting from irregularly measured O₂ concentrations at this depth. The differences in O₂ consumption between negative control and inoculated tubes at t₀ occurred through the temporal distance and between the measurements and the influence of the fast diffusion.
Figure 6. Selected Fe$^{2+}$ concentration depth profiles for gradient tubes inoculated with an enrichment of freshwater microaerophilic Fe(II)-oxidizers from Lake Constance, Germany (A) and (B) or with an isolate of a marine Fe(II)-oxidizer from Aarhus Bay, Denmark (C) and (D). Open symbols and dashed lines represent negative control tubes, closed symbols and solid lines inoculated tubes. Error bars show the standard deviation of the triplicate measurements. The colors display the different times of measurements starting at the day of inoculation ($t_0$). Open symbols and dashed lines represent negative control tubes, closed symbols and solid lines inoculated tubes. (A) Profiles of Gibbs free energy, (B) rate of homogeneous Fe$^{2+}$ oxidation, (C) half-life of homogeneous Fe$^{2+}$ oxidation, (D) comparison between homogeneous and heterogeneous Fe$^{2+}$ concentration in 16 mm depth over time. The depth was chosen according to the approximate level where the growth band formed in inoculated tubes. ($t_0 =$ day of inoculation; $t_2 =$ day 2, $t_6 =$ day 6 after inoculation)
FeS is slightly different and FeS loses its ability to release Fe$^{2+}$ by aging. The quality of the FeS influences the solubility and diffusion of Fe$^{2+}$ leading to shifts of the optimum growth zone for microaerophilic Fe(II)-oxidizers. We have observed in the past that the rate of mixing Fe(II) and sulfide, the washing procedure (frequency and length of washing steps) and the storage of the FeS determines its suitability as Fe(II)-source in gradient tubes (unpublished data). Besides that, the medium composition and the cell number and activity of the inoculated strains determine the position of the Fe(III) mineral accumulations and lead to other forms of Fe(III) mineral accumulations than the shape of the classical growth bands as shown by e.g. Emerson (Emerson and Moyer 1997; Emerson and Floyd 2005) or in Fig. 3A and D. Due to these uncertainties, a quantitative visual evaluation between different Fe(II)-sources, strains or media cannot be done. However, gradient tubes are very suitable for bacterial cultivation and geochemical determination of optimum O$_2$ and Fe$^{2+}$ requirements of Fe(II)-oxidizing bacteria. The Fe(II)-sources FeS and ZVI showed the best results regarding growth of freshwater and marine microaerophilic Fe(II)-oxidizing bacteria in gradient tubes and worked reliably.

**Detection of optimal geochemical conditions for the growth of microaerophilic Fe(II)-oxidizers**

Microaerophilic Fe(II)-oxidizing bacteria are in direct competition to chemical Fe(II) oxidation. Druschel et al. (2008) pointed out that chemical Fe(II) oxidation dominates at a O$_2$ concentrations of 275 $\mu$M and at 50 $\mu$M the biotic Fe(II) oxidation rate was faster than the abiotic rate. This fits well to our observation that Fe(III) mineral accumulations, which are produced by Fe(II)-oxidizing bacteria, occurred first in regions of O$_2$ concentrations of approximately 20–40 $\mu$M (Fig. 4). As most of the Fe(III) minerals accumulated very close to the Fe(II)-source at the bottom of the gradient tubes, a characteristic bend of the O$_2$ profiles in inoculated gradient tubes could not be observed as seen in the literature (Emerson and Moyer 1997; Edwards et al. 2003; Roden et al. 2004) where no O$_2$ was detected below cell growth bands. However, the tested freshwater culture was not completely pure. This might lead to slightly different conditions. The position of the Fe(III) mineral accumulations can be explained by the solubility of the Fe(II)-source, the faster O$_2$ diffusion (2.4 $\times$ 10$^{-9}$ m$^2$ s$^{-1}$ (McMillan and Wang 1990)) compared to Fe$^{2+}$ diffusion (0.719 $\times$ 10$^{-9}$ m$^2$ s$^{-1}$ (Lide 2008)), but also by the specific inoculated bacteria. The bacteria might also be responsible for the varying shapes of the Fe(III) mineral accumulations that were often not occurring as typical flat band by potential formation of different geochemical niches with optimal growth conditions.

The results indicate that most Fe(II) gets oxidized chemically. Differences in the O$_2$ concentrations between inoculated and negative control tubes could be observed only in the beginning of the incubation and within a short timeframe when first Fe(III) mineral accumulations occurred (Fig. 8). This illustrates the competitive pressure of microaerophilic Fe(II)-oxidizers towards chemical Fe(II) oxidation. The main O$_2$ consumption zone in the gradient tubes shifts downwards relatively fast. Starting at $t_2$, O$_2$ solely is consumed in the lower part of the gradient tube and there are no significant differences in O$_2$ consumption between inoculated and negative control tubes, which reinforce the assumption that the microorganisms are most of the time in strong competition with the chemical O$_2$ consumption.

When Fe(III) minerals precipitated as a result of microbial or homogeneous chemical Fe(II) oxidation, they serve as a catalyst for further chemical Fe(II) oxidation (autocatalysis) and increase the rate of chemical Fe(II) oxidation (Stumm and Sulzberger 1992; Park and Dempsey 2005; Melton et al. 2014). This heterogeneous Fe(II) oxidation thus increases the contribution of chemical Fe(II) oxidation to the overall Fe(II) oxidation. Energetic and kinetic constraints support the hypothesis that best growth conditions for Fe(II)-oxidizing bacteria are found to be in the proximity of the Fe(II)-source in the first days after inoculation where not only the Fe$^{2+}$ concentration still is sufficient for bacterial growth but also more energy can be obtained from the oxidation of Fe$^{2+}$ for the bacterial metabolisms. Additionally, the bacteria at this location have the ability to compete with the half-life of the chemical Fe$^{2+}$ oxidation that decreases dramatically over time, especially due to heterogeneous Fe$^{2+}$ oxidation. The agreement between the Gibbs free energy and homogeneous Fe$^{2+}$ oxidation rate profiles (Fig. 7A and B) in abiotic and inoculated gradient tubes also indicate that most Fe$^{2+}$ in the gradient tube top layer is abiotically depleted.

Based on differences of the shape of the O$_2$ profiles in the inoculated tubes and the comparison of these O$_2$ profiles to the control tubes, it can be concluded that significant biotic Fe(II) oxidation is only dominating in the first hours to days, when distinct Fe(III) mineral accumulations occurred, which were shown to be related to bacterial growth as demonstrated by microscopic cell counts. The number of Fe(II)-oxidizing bacteria indeed increased most (Fig. 2), when spreading of the Fe(III) mineral accumulations could visually be observed. Based on these observations, bacterial cultures should therefore be transferred shortly after occurrence of distinct Fe(III) mineral accumulations to a new gradient tube before chemical Fe(II) oxidation becomes too dominant, in order to enhance the chance for isolation of microaerophilic Fe(II)-oxidizers.

**Suggestions for cultivation and isolation of microaerophilic Fe(II)-oxidizing bacteria from environmental samples**

In the present study, the most suitable Fe(II)-sources for cultivation of freshwater and marine microaerophilic Fe(II)-oxidizers have been FeS and ZVI. Fe(III) mineral accumulations regularly occurred in inoculated gradient tubes using these Fe(II)-sources. Visual observations also showed that FeS and ZVI were less sensitive to chemical oxidation by O$_2$ than FeCO$_3$ and FeCl$_2$. The Fe(II)-sources FeCO$_3$ and FeCl$_2$ immediately began to oxidize based on the appearance of rust-colored oxides upon contact with air. However, it should be noted that using FeS or ZVI as Fe(II)-sources might stimulate the growth of other abundant microorganisms. Besides being a Fe$^{2+}$ source, FeS might also serve as sulfide source for microaerophilic sulfide-oxidizing bacteria (Nelson and Jannasch 1983; Gevertz et al. 2000). If sulfate gets produced biotically in these tubes, optimal conditions for heterotrophic sulfate reducers are prevalent as well as they can use carbon from organic compounds present in the agar. Due to hydrogen gas production during Fe(0) corrosion, gradient tubes using ZVI as bottom source might enrich bacteria that are capable of using hydrogen as electron donor (Jannasch and Motl 1985; Dannenberg et al. 1992; Coleman et al. 1993). Additionally, it should be kept in mind that agar, which is used for the stabilization of the top layer of gradient tubes, is an organic substance that could be used for growth by heterotrophic bacteria. This is especially true for marine samples, as agar is prepared from algae that naturally serve as organic carbon source for marine microorganisms. Therefore, we suggest both, short-term transfers to fresh gradient tubes, and the use of different Fe(II)-sources for isolation of microaerophilic Fe(II)-oxidizing bacteria, namely.
Figure 8. O₂ and Fe²⁺ concentration depth profiles for gradient tubes containing MWMM and an FeS bottom layer at t₀, t₂ and t₆ (t₀ = day of inoculation, t₂ = day 2, t₆ = day 6 after inoculation). Open symbols and dashed lines represent negative control tubes, closed symbols and solid lines inoculated tubes. Error bars show the standard deviation of the triplicate measurements. The sketches next to the profiles show the look of the gradient tubes at the respective measurement time points.
using alternating FeS and ZVI as Fe(II)-source. For enhancing the chance to remove heterotrophic bacteria from the sample, the bacterial cultures could be transferred to petri dishes containing only medium and ZVI powder (McBeth et al. 2011). Enrichment in the so-called gradient plates was successfully applied in the literature (Emerson and Weiss 2004; McBeth et al. 2011; Laufer et al. 2016). Freshly synthesized FeCO₃ according to Hallbeck, Stähli and Pedersen (1993) could also be used to suppress the growth of bacteria that are additionally feeding on substrates that are released from the Fe(II)-source, e.g. S-species. However, we recommend doing transfers between FeS and ZVI in gradient tubes and gradient plates as FeCO₃ is quite sensitive towards oxidation by O₂ and only poorly releases Fe²⁺, especially if it is not freshly synthesized.
