#### Abstract

Probabilistic solvers for ordinary differential equations (ODEs) have emerged as an efficient framework for uncertainty quantification and inference on dynamical systems. In this work, we explain the mathematical assumptions and detailed implementation schemes behind solving high-dimensional ODEs with a probabilistic numerical algorithm. This has not been possible before due to matrix-matrix operations in each solver step, but is crucial for scientifically relevant problems - most importantly, the solution of discretised partial differential equations. In a nutshell, efficient high-dimensional probabilistic ODE solutions build either on independence assumptions or on Kronecker structure in the prior model. We evaluate the resulting efficiency on a range of problems, including the probabilistic numerical simulation of a differential equation with millions of dimensions.

## 1 INTRODUCTION

Problem Statement This paper discusses a class of algorithms that computes the solution of initial value problems based on ordinary differential equations (ODEs), i.e. finding a function $y$ that satisfies

$$
\begin{equation*}
\dot{y}(t)=f(y(t), t), \tag{1}
\end{equation*}
$$

for all $t \in\left[t_{0}, t_{\text {max }}\right]$, as well as the initial condition $y\left(t_{0}\right)=y_{0} \in \mathbb{R}^{d}$. Usually, $f$ is non-linear, in which case the solution of Eq. (1) cannot generally be derived in closed form and has to be approximated numerically. We continue the work of probabilistic numerical algorithms for ODEs (Schober et al., 2019; Tronarp et al., 2019; Kersting et al., 2020b; Tronarp et al., 2021;

[^0]Bosch et al., 2021; Krämer and Hennig, 2020). Like other filtering-based ODE solvers ("ODE filters"), the algorithm used herein translates numerical approximation of ODE solutions to a problem of probabilistic inference. The resulting (approximate) posterior distribution quantifies the uncertainty associated with the unavoidable discretisation error (Bosch et al., 2021) and provides a language that integrates well with other data inference schemes (Kersting et al., 2020a; Schmidt et al., 2021). The main difference to prior work is that we focus on the setting where the dimension $d$ of the ODE is high, that is, say, $d \gg 100$. (It is not clearly defined at which point an ODE counts as highdimensional, but $d \approx 100$ is already a scale of problems in which previous state-of-the-art probabilistic ODE solvers faced computational challenges.)

Motivation And Impact High-dimensional ODEs describe the interaction of large networks of dynamical systems and appear in many disciplines in the natural sciences. The perhaps most prominent example arises in the simulation of discretised partial differential equations. There, the dimension of the ODE equals the number of grid points used to discretise the problem (with e.g. finite differences; Schiesser, 2012). More recently, ODEs gained popularity in machine learning through the advent of neural ODEs (Chen et al., 2018), continuous normalising flows (Grathwohl et al., 2018), or physics-informed neural networks (Raissi et al., 2019). With the growing complexity of the model, each of the above can quickly become high-dimensional. If such use cases shall gain from probabilistic solvers, fast algorithms for large ODE systems are crucial.

Prior Work And State-of-the-Art Many nonprobabilistic ODE solvers, for example, explicit RungeKutta methods, have a computational complexity linear in the ODE dimension $d$ (Hairer et al., 1993). Explicit Runge-Kutta methods are often the default choices in ODE solver software packages. Compared to the efficiency of the methods provided by DifferentialEquations.jl (Rackauckas and Nie, 2017), SciPy (Virtanen et al., 2020), or Matlab (Shampine and Reichelt, 1997), probabilistic methods have lacked behind so far. In-

Figure 1: Simulating a high-dimensional ODE: Probabilistic solution of a discretised FitzHugh-Nagumo PDE model (Ambrosio and Françoise, 2009). Means (a-e) and standard-deviations (f-j), $t_{0}=0$ (left) to $t_{\max }=20$ (right). The patterns in the uncertainties match those in the solution. The simulated ODE is 125 k -dimensional.
tuitively, ODE filters are a fusion of ODE solvers and Gaussian process models-two classes of algorithms that suffer from high dimensionality. More precisely, the problem is that probabilistic solvers require matrixmatrix operations at each step. The matrices have $O\left(d^{2}\right)$ entries, which leads to $O\left(d^{3}\right)$ complexity for a single solver step and has made the solution of highdimensional ODEs impossible. ODE filters are essentially nonlinear, approximate Gaussian process inference schemes (with a lot of structure). As in the GP community (e.g. Quiñonero-Candela and Rasmussen, 2005), the path to low computational cost in these models is via factorisation assumptions.

Contributions Our main contribution is to prove in which settings ODE filters admit an implementation in $O(d)$ complexity. Thereby, they become a class of algorithms comparable to explicit Runge-Kutta methods not only in estimation performance (error contraction as a function of evaluations of $f$; Kersting et al., 2020b; Tronarp et al., 2021) but also in computational complexity (cost per evaluation of $f$ ). The resulting algorithms deliver uncertainty quantification and other benefits of probabilistic ODE solvers on high-dimensional ODEs (see Fig. 1. The ODE from this figure will be explored in more detail in Section 5). The key novelties of the present work are threefold:

1. Acceleration via independence: A-priori, ODE filters commonly assume independent ODE dimensions (e.g. Kersting et al., 2020b). We single out those inference schemes that naturally preserve
independence. Identification of independencepreserving ODE solvers is helpful because each ODE dimension can be updated separately. The performance implications are that a single matrixmatrix operation with $O\left(d^{2}\right)$ entries is replaced with $d$ matrix-matrix operations with $O(1)$ entries. In other words, $O(d)$ instead of $O\left(d^{3}\right)$ complexity for a single solver step. This is Proposition 3.
2. Calibration of multivariate output-scales: A single ODE system often models the interaction between states that occur on different scales. It is useful to acknowledge differing output scales in the "diffusivity" of the prior (details below). We generalise the calibration result by Bosch et al. (2021) to the class of solvers that preserve the independence of the dimensions. This is Proposition 2.
3. Acceleration via Kronecker structure: Sometimes, prior independence assumptions may be too restrictive. For instance, one might have prior knowledge of correlations between ODE dimensions (Example 4 in Section 4). Fortunately, a subset of probabilistic ODE solvers can exploit and preserve Kronecker structure in the system matrices of the state space. Preserving the Kronecker structure brings over the performance gains from above to dependent priors. This is Proposition 6.

Additional minor contributions are detailed where they occur. To demonstrate the scalability of the resulting algorithm, the experiments in Section 5 showcase simulations of ODEs with dimension $d \sim 10^{7}$.

## 2 ODE FILTER SETUP

The following section details the technical setup of an ODE filter, including the prior (Section 2.1) and information model (Section 2.2), as well as a selection of relevant practical considerations (Section 2.3).

### 2.1 Prior Model

The following is standard for probabilistic ODE solvers, and therefore essentially identical to the presentation by e.g. Schober et al. (2019). Herein, however, we place a stronger emphasis on Kronecker- and independencestructures in the system matrices compared to prior work. Both are important for the theoretical statements below. Särkkä (2013) or Särkkä and Solin (2019) provide a comprehensive explanation of the mathematical concepts regarding inference in state-space models.

## Stochastic Process Prior On The ODE Solution

 Let $Y:=\left(Y^{i}\right)_{i=1}^{d}=\left(Y_{0}^{i}, \ldots, Y_{\nu}^{i}\right)_{i=1}^{d}$ solve the linear, time-invariant stochastic differential equation (SDE)$$
\begin{equation*}
\mathrm{d} Y(t)=A Y(t) \mathrm{d} t+B \mathrm{~d} W(t) \tag{2}
\end{equation*}
$$

subject to a Gaussian initial condition

$$
\begin{equation*}
Y\left(t_{0}\right) \sim \mathcal{N}\left(m_{0}, C_{0}\right) \tag{3}
\end{equation*}
$$

for some $m_{0}$ and $C_{0}:=\Gamma \otimes \breve{C}_{0}$. The SDE is driven by a $d$-dimensional Wiener process $W$ with diffusion $\Gamma \in \mathbb{R}^{d \times d}$ and governed by the system matrices

$$
\begin{equation*}
A:=I_{d} \otimes \breve{A}, \quad \breve{A}:=\sum_{q=0}^{\nu-1} e_{q} e_{q+1}^{\top}, \quad B:=I_{d} \otimes e_{\nu} \tag{4}
\end{equation*}
$$

where $e_{q} \in \mathbb{R}^{\nu+1}$ is the $q$-th basis vector. The zeroth component of $Y,\left(Y_{0}^{i}\right)_{i=1}^{d}$, is an integrated Wiener process. With such $A$ and $B$, the $q$-th component $\left(Y_{q}^{i}\right)_{i=1}^{d}$ models the $q$-th derivative of the integrated Wiener process. Similar SDEs can be written down for e.g. the integrated Ornstein-Uhlenbeck process or the Matérn process (the only differences would be additional nonzero entries in $A$ ). If $\Gamma$ were diagonal, the Kronecker structure in $A$ and $B$ would imply prior pairwise independence between $Y^{i}$ and $Y^{j}, i \neq j$. Section 3 uses the diagonality assumption to reveal the efficient implementation of a class of ODE filters. Section 4 allows $\Gamma$ to be any symmetric, positive definite matrix, which is why we do not make strong assumptions on $\Gamma$ yet.

Discretisation Let $\mathbb{T}=\left(t_{0}, \ldots, t_{N}\right)$ be some timegrid with step-size $h_{n}:=t_{n+1}-t_{n}$. While for the presentation, we assume a fixed grid, practical implementations choose $t_{n}$ adaptively. Reduced to $\mathbb{T}$, due to the Markov property, the process $Y$ becomes

$$
\begin{equation*}
Y\left(t_{n+1}\right) \mid Y\left(t_{n}\right) \sim \mathcal{N}\left(\Phi\left(h_{n}\right) Y_{n}, \Sigma\left(h_{n}\right)\right) \tag{5}
\end{equation*}
$$

for matrices $\Phi\left(h_{n}\right)$ and $\Sigma\left(h_{n}\right)$, which are defined as

$$
\begin{align*}
& \Phi\left(h_{n}\right)=\exp \left(A h_{n}\right)  \tag{6a}\\
& \Sigma\left(h_{n}\right)=\int_{0}^{h_{n}} \Phi\left(h_{n}-\tau\right) B \Gamma B^{\top} \Phi\left(h_{n}-\tau\right)^{\top} \mathrm{d} \tau \tag{6~b}
\end{align*}
$$

The definition of $\Phi\left(h_{n}\right)$ uses the matrix exponential. $\Phi\left(h_{n}\right)$ inherits the block diagonal structure from $A$,

$$
\begin{equation*}
\Phi:=I_{d} \otimes \breve{\Phi}\left(h_{n}\right), \quad \breve{\Phi}\left(h_{n}\right)=\exp \left(\breve{A} h_{n}\right) \tag{7}
\end{equation*}
$$

and $\Sigma$ has a Kronecker factorisation similar to $C_{0}$,

$$
\begin{align*}
& \Sigma\left(h_{n}\right):=\Gamma \otimes \breve{\Sigma}\left(h_{n}\right)  \tag{8a}\\
& \breve{\Sigma}\left(h_{n}\right):=\int_{0}^{h_{n}} \breve{\Phi}\left(h_{n}-\tau\right) e_{\nu} e_{\nu}^{\top} \breve{\Phi}\left(h_{n}-\tau\right)^{\top} \mathrm{d} \tau . \tag{8b}
\end{align*}
$$

The discretisation allows efficient extrapolation from $t_{n}$ to $t_{n+1}$. Let $Y\left(t_{n}\right) \sim \mathcal{N}\left(m_{n}, C_{n}\right)$. Then,

$$
\begin{equation*}
Y\left(t_{n+1}\right) \sim \mathcal{N}\left(m_{n+1}^{-}, C_{n+1}^{-}\right) \tag{9}
\end{equation*}
$$

with mean and covariance

$$
\begin{align*}
m_{n+1}^{-} & =\Phi\left(h_{n}\right) m_{n}  \tag{10a}\\
C_{n+1}^{-} & =\Phi\left(h_{n}\right) C_{n} \Phi\left(h_{n}\right)^{\top}+\Sigma\left(h_{n}\right) \tag{10b}
\end{align*}
$$

For improved numerical stability, probabilistic ODE solvers compute this prediction in square root form, which means that only square root matrices of $C_{n}$ and $C_{n+1}^{-}$are propagated without ever forming full covariance matrices (Krämer and Hennig, 2020; Grewal and Andrews, 2014). Supplement A recalls details about square root implementations of ODE filters.

### 2.2 Information Model

Information Operator The information operator

$$
\begin{equation*}
\mathcal{I}(Y)(t):=\dot{Y}(t)-f(Y(t), t) \tag{11}
\end{equation*}
$$

known as the local defect (Gustafsson, 1992), captures "how well (a sample from) $Y$ solves the given ODE"-if this value is large, the current state is an inaccurate approximation, and if it is small, $Y$ provides a good estimate of the truth. The goal is to make the defect as small as possible over the entire time domain.

Artificial Data The local defect $\mathcal{I}$ can be kept small by conditioning $Y$ on $\mathcal{I}(Y)(t) \stackrel{!}{=} 0$ on "many" gridpoints. Due to the regular prior and the regularitypreserving information operator $\mathcal{I}$, conditioning the prior on a zero-defect leads to an accurate ODE solution (Tronarp et al., 2021). Altogether, the probabilistic ODE solver targets the posterior distribution

$$
\begin{equation*}
p\left(Y \mid\left\{\mathcal{I}(Y)\left(t_{n}\right)=0\right\}_{n=0}^{N}, Y_{0}\left(t_{0}\right)=y_{0}\right) \tag{12}
\end{equation*}
$$

(Recall from Eq. (2) that lower indices in $Y$ refer to the derivative, i.e. $Y_{0}$ is the integrated Wiener process, and $Y_{q}$ its $q$-th derivative.) We call the posterior in Eq. (12) the probabilistic $O D E$ solution. Unfortunately, a nonlinear vector field $f$ implies a nonlinear information operator $\mathcal{I}$. Thus, the exact posterior is intractable.

Linearisation A tractable approximation of the probabilistic ODE solution is available through linearisation. Linearising $f$ indirectly linearises $\mathcal{I}$, and the corresponding probabilistic ODE solution arises via Gaussian inference. Let $F_{y}$ be (an approximation of) the Jacobian of $f$ with respect to $y$. One can approximate the ODE vector field with a Taylor series

$$
\begin{equation*}
f(y) \approx \hat{f}_{\xi}(y):=f(\xi)+F_{y}(\xi)(y-\xi) \tag{13}
\end{equation*}
$$

at some $\xi \in \mathbb{R}^{d}$. Let $E_{q}:=I_{d} \otimes e_{q}$ be the projection matrix that extracts the $q$-th derivative from the full state $Y$. In other words, $Y_{0}=E_{1} Y$. Eq. (13) implies a linearisation of $\mathcal{I}$ at some $\eta \in \mathbb{R}^{d(\nu+1)}$,

$$
\begin{equation*}
\mathcal{I}(Y)(t) \approx \hat{\mathcal{I}}_{\eta}(Y)(t):=H(t) Y(t)+b(t) \tag{14}
\end{equation*}
$$

with linearisation matrices

$$
\begin{align*}
H(t) & :=E_{1}-F_{y}\left(E_{0} \eta, t\right) E_{0},  \tag{15a}\\
b(t) & :=F_{y}\left(E_{0} \eta, t\right) E_{0} \eta-f\left(E_{0} \eta, t\right) . \tag{15b}
\end{align*}
$$

$\hat{\mathcal{I}}_{\eta}$ is linear in $Y(t)$. Therefore, the approximate probabilistic ODE solution becomes tractable with Gaussian filtering and smoothing once $\hat{\mathcal{I}}_{\eta}$ is plugged into Eq. (12) (Särkkä, 2013; Tronarp et al., 2019). At $t_{n}, \eta$ is usually the predicted mean $m_{n}^{-}$, which yields the extended Kalman filter (Särkkä, 2013). For ODE filters, there are three relevant versions of $F_{y}$ :

1. EKO: Use the zero-matrix to approximate the Jacobian, $F_{y} \equiv 0$, which has been a common choice since early work on ODE filters (Schober et al., 2019; Kersting et al., 2020b), and implies a zerothorder approximation of $f$ (Tronarp et al., 2019).
2. EK1: Use the full Jacobian $F_{y}=\nabla_{y} f$, which amounts to a first-order Taylor approximation of the ODE vector field (Tronarp et al., 2019). In its general form, the EK1 does not fit the assumptions made below and can thus does not immediately scale to high dimensions. Instead, we introduce the following variant:
3. Diagonal EK1: Use the diagonal of the full Jacobian, $F_{y}=\operatorname{diag}\left(\nabla_{y} f\right)$. This choice conserves the efficiency of the EK0 to a solver that uses Jacobian information. The diagonal EK1 is another minor contribution of the present work. The EK1 is more stable than the EK0 (Tronarp et al., 2019). Section 5 empirically investigates how much stability using only the diagonal of the Jacobian provides.

Measurement And Correction A probabilistic ODE solver step consists of an extrapolation, measurement, and correction phase. Extrapolation has been explained in Eqs. (9) and (10) above. Denote

$$
\begin{equation*}
Y_{n+1}^{-}:=Y\left(t_{n+1}\right) \sim \mathcal{N}\left(m_{n+1}^{-}, C_{n+1}^{-}\right) \tag{16}
\end{equation*}
$$

The measurement phase approximates

$$
\begin{equation*}
Z_{n+1}:=\hat{\mathcal{I}}_{m_{n+1}^{-}}\left(Y_{n+1}^{-}\right)\left(t_{n+1}\right) \approx \mathcal{I}\left(Y_{n+1}^{-}\right)\left(t_{n+1}\right) \tag{17}
\end{equation*}
$$

by exploiting the linearisation matrices $H$ and $b$,

$$
\begin{align*}
Z_{n+1} & \sim \mathcal{N}\left(z_{n+1}, S_{n+1}\right)  \tag{18a}\\
z_{n+1} & :=H\left(t_{n+1}\right) m_{n+1}^{-}+b\left(t_{n+1}\right),  \tag{18b}\\
S_{n+1} & :=H\left(t_{n+1}\right) C_{n+1}^{-} H\left(t_{n+1}\right)^{\top} . \tag{18c}
\end{align*}
$$

$Z_{n+1}$ will be used for calibration (details below). The extrapolated random variable is then corrected as

$$
\begin{align*}
Y_{n+1} & \sim \mathcal{N}\left(m_{n+1}, C_{n+1}\right),  \tag{19a}\\
m_{n+1} & :=m_{n+1}^{-}-C_{n+1}^{-} H\left(t_{n+1}\right)^{\top} S_{n+1}^{-1} z_{n+1},  \tag{19b}\\
C_{n+1} & :=\Xi C_{n+1}^{-} \Xi^{\top},  \tag{19c}\\
\Xi & :=I-C_{n+1}^{-} H\left(t_{n+1}\right)^{\top} S_{n+1}^{-1} H\left(t_{n+1}\right) . \tag{19d}
\end{align*}
$$

The update in Eqs. (19c) and (19d) is the Joseph update (Bar-Shalom et al., 2004). In practice, we never form the full $C_{n+1}$ but compute only the square root matrix by applying $\Xi$ to the square root matrix of $C_{n+1}^{-}$. It is not a Cholesky factor (because it is not lower triangular), but generic square root matrices suffice for numerically stable implementation of probabilistic ODE solvers (Krämer and Hennig, 2020).

### 2.3 Practical Considerations

Let us conclude with brief pointers to further practical considerations that are important for efficient probabilistic ODE solutions.
$\diamond$ Initialisation: The ODE filter state models a stack of a state and the first $\nu$ derivatives. The stability of the probabilistic ODE solver depends on the accurate initialisation of all derivatives. The current state of the art is to use Taylor-mode automatic differentiation (Krämer and Hennig, 2020; Griewank and Walther, 2008), whose complexity scales exponentially with the dimension of the ODE. Instead, we initialise the solver by inferring

$$
\begin{equation*}
p\left(Y\left(t_{0}\right) \mid Y_{0}\left(\tau_{m}\right)=\hat{y}\left(\tau_{m}\right), m=0, \ldots, \nu\right) \tag{20}
\end{equation*}
$$

on $\nu+1$ small steps $\tau_{0}, \ldots, \tau_{\nu}$ where the $\hat{y}\left(\tau_{m}\right)$ are computed with e.g. a Runge-Kutta method. This is a slight generalisation of the strategy used by Schober et al. (2019) (also refer to Schober et al. (2014); Gear (1980)), in the sense that we formulate this initialisation as probabilistic inference instead of setting the first few means manually.
$\diamond$ Error estimation: Comprehensive explanation of error estimation and step-size adaptation is out of scope for the present work; we refer the reader to Schober et al. (2019) and Bosch et al. (2021).

## 3 INDEPENDENT PRIOR MODELS ACCELERATE ODE SOLVERS

This section establishes the main idea of the present work: probabilistic ODE solvers are fast and efficient when the prior models each dimension independently.

### 3.1 Assumptions

Independent dimensions stem from a diagonal $\Gamma$.
Assumption 1. Assume that the diffusion $\Gamma$ of the Wiener process in Eq. (2) is a diagonal matrix.

Assumption 1 implies that the initial covariance $C_{0}$ (Eq. (3)) is the Kronecker product of a diagonal matrix with another matrix, thus block diagonal. Assumption 1 is not very restrictive; in prior work on ODE filters, $\Gamma$ was always either $\Gamma=\gamma^{2} I$ for some $\gamma>0$ (Schober et al., 2019; Tronarp et al., 2019; Kersting et al., 2020b; Bosch et al., 2021; Tronarp et al., 2021; Krämer and Hennig, 2020), or diagonal (Bosch et al., 2021).

### 3.2 Calibration

Tuning the diffusion $\Gamma$ is crucial to obtain accurate posterior uncertainties. As announced in Section 2, the mathematical assumptions for calibrating $\Gamma$ coincide with the assumptions that lead to an efficient ODE filter. Thus, we discuss $\Gamma$ before proving the linear complexity of probabilistic solvers under Assumption 1.

Four Approaches Recall the observed random variable $Z_{n}$ (Eq. (17)). ODE filters calibrate $\Gamma$ with quasi-maximum-likelihood-estimation (quasi-MLE): Consider the prediction error decomposition (Schweppe, 1965),

$$
\begin{align*}
p\left(\left\{Z_{n}\right\}_{n=0}^{N}\right) & =p\left(Z_{0}\right) \prod_{n=0}^{N-1} p\left(Z_{n+1} \mid Z_{n}\right)  \tag{21a}\\
& \approx \mathcal{N}\left(z_{0}, S_{0}\right) \prod_{n=0}^{N-1} \mathcal{N}\left(z_{n+1}, S_{n+1}\right) \tag{21b}
\end{align*}
$$

$\Gamma$ is a quasi-MLE if it maximises Eq. (21b). The specific choice of calibration depends on respective model for $\Gamma$, and reduces to one of four approaches: on the one hand, fixing and calibrating a time-constant $\Gamma$ versus allowing a time-varying $\Gamma$; on the other hand, choosing a scalar diffusion $\Gamma=\gamma^{2} I$ versus choosing a vectorvalued diffusion $\Gamma=\operatorname{diag}\left(\gamma^{1}, \ldots, \gamma^{d}\right)$. Roughly speaking, a time-varying, vector-valued diffusion allows for the
greatest flexibility in the probabilistic model. One contribution of the present work is to extend the vectorvalued diffusion results by Bosch et al. (2021) to a slightly broader class of solvers (Proposition 2 below). Scalar diffusion will reappear in Section 4 below. Timeconstant diffusion is addressed in Supplement B.

Time-Varying Diffusion Allowing $\Gamma$ to change over the time-steps, all measurements before time $t_{n}$ are independent of $\Gamma_{n}$. Under the assumption of an error-free previous state (which is common for hyperparameter calibration in ODE solvers), a local quasi-MLE for $\Gamma_{n}=\gamma_{n}^{2} I$ arises as (Schober et al., 2019)

$$
\begin{equation*}
\hat{\gamma}_{n}^{2}:=\frac{1}{d} z_{n}\left[H\left(t_{n}\right) \Sigma\left(h_{n}\right) H\left(t_{n}\right)^{\top}\right]^{-1} z_{n} \tag{22}
\end{equation*}
$$

This can be extended to a quasi-MLE for the EK0 with vector-valued $\Gamma_{n}=\operatorname{diag}\left(\gamma_{n}^{1}, \ldots, \gamma_{n}^{d}\right)$ (Bosch et al., 2021)

$$
\begin{equation*}
\left(\hat{\gamma}_{n}^{i}\right)^{2}:=\left(z_{n}^{i}\right)^{2} /\left[H\left(t_{n}\right) \Sigma\left(h_{n}\right) H\left(t_{n}\right)^{\top}\right]_{i i} \tag{23}
\end{equation*}
$$

for all $i=1, \ldots, d$. In this work, we generalise the EK0 requirement to Assumption 1 and a diagonal Jacobian.
Proposition 2. Under Assumption 1 and for diagonal $F_{y}$, the estimators $\left(\hat{\gamma}_{n}^{i}\right)_{i}$ in Eq. (23) are quasi-MLEs.

Sketch of the proof. Two ideas are relevant: (i) a diagonal Jacobian implies a block diagonal $H\left(t_{n}\right)$ and a diagonal $H\left(t_{n}\right) \Sigma\left(h_{n}\right) H\left(t_{n}\right)^{\top}$ (which will be proved formally in Proposition 3 below); (ii) the local evidence, i.e. the probability of $\mathcal{N}\left(z_{n}, S_{n}\right)$ being zero, decomposes into a sum over the coordinates. Maximising each summand with respect to $\gamma_{n}^{i}$ yields the claim.

A very similar case can be made for time-constant diffusion (see Supplement B). Proposition 2 is a generalisation of the results by Bosch et al. (2021) in the sense that Proposition 2 is not restricted to the EK0.

### 3.3 Complexity

Now, with calibration in place, we can discuss the computational complexity of ODE filters under Assumption 1. The following proposition establishes that for diagonal Jacobians, a single solver step costs $O(d)$.
Proposition 3. Suppose that Assumption 1 is in place. If the Jacobian of the ODE is (approximated as) a diagonal matrix, then a single step with a filtering-based probabilistic $O D E$ solver costs $O\left(d \nu^{3}\right)$ in floating-point operations, and $O\left(d \nu^{2}\right)$ in memory.

Proof. Let $Y_{n} \sim \mathcal{N}\left(m_{n}, C_{n}\right)$. Assume that $C_{n}$ is block diagonal. We show that block diagonality is preserved through a step, and since by Assumption 1, $C_{0}$ is block diagonal, we do not lose generality. Recall $\Phi\left(h_{n}\right)$ and
$\Sigma\left(h_{n}\right)$ from Eqs. (5) and (6). $\Phi\left(h_{n}\right)$ is block diagonal, and since $\Gamma_{n}$ is diagonal, $\Sigma\left(h_{n}\right)$ is block diagonal.
(i) Extrapolate the mean: The mean is extrapolated according to Eq. (10a), which costs $O\left(d \nu^{2}\right)$, because of the block diagonal $\Phi\left(h_{n}\right)$. Each dimension is extrapolated independently.
(ii) Evaluate the $O D E$ : Next, $H=H\left(t_{n+1}\right)$ and $b=$ $b\left(t_{n+1}\right)$ from Eq. (15) are assembled, which involves evaluating $f$ and $F_{y}$ at $\xi:=E_{0} m_{n+1}^{-}\left(E_{0}\right.$ is a projection matrix and can be implemented as array indexing, so $\xi$ comes at negligibily low cost). $F_{y}=\operatorname{diag}\left(F_{y}^{1}, \ldots F_{y}^{d}\right)$ is a diagonal matrix, therefore

$$
\begin{equation*}
H=\operatorname{blockdiag}\left(H^{1}, \ldots, H^{d}\right) \tag{24}
\end{equation*}
$$

is block diagonal with blocks

$$
\begin{equation*}
H^{i}:=e_{1}-e_{0} F_{y}^{i}, \quad i=1, \ldots, d \tag{25}
\end{equation*}
$$

(recall the basis vectors $e_{q}$ from Eq. (4)). The block diagonal $H$ has been pre-empted in Proposition 2 above.
(iii) Calibrate $\Gamma$ : The cost of assembling the quasiMLE for $\Gamma_{n+1}$ according to Eq. (22) or Eq. (23) is $O(d)$, because the matrix to be inverted is diagonal.
(iv) Extrapolate the covariance: The covariance can be extrapolated dimension-by-dimension as well, because $C_{n}, \Phi\left(h_{n}\right)$, and $\Sigma\left(h_{n}\right)$ are all block diagonal with the same block structure: $d$ square blocks with $\nu+1$ rows and columns; recall Eq. (10b). In reality, the matrixmatrix multiplication is replaced by a QR decomposition; we refer to Supplement A. 1 for details on square root implementation. Using either strategy - square root or traditional implementation-extrapolating the covariance costs $O\left(d \nu^{3}\right)$ and $C_{n+1}^{-}$is block diagonal.
(v) Measure: Computing the mean of $Z_{n+1}$ (recall Eqs. (17) and (18)) costs $O(d)$. The covariance $S_{n+1}$ of $Z_{n+1}$ is diagonal, since $H$ and $C_{n+1}^{-}$are block diagonal. Thus, assembling and inverting $S_{n+1}$ costs $O(d)$.
(vi) Correct mean and covariance: The mean is corrected according to Eq. (19b), which - since $S_{n+1}$ is diagonal - costs $O(d \nu)$. The covariance is corrected according to Eqs. (19c) and (19d), the complexity of which hinges on the structure of $\Xi$ (Eq. (19d)): due to the block diagonal $C_{n+1}^{-}, H$, and $S_{n+1}, \Xi$ is block diagonal again, and correcting the covariance costs $O\left(d \nu^{3}\right)$. The square root matrix of $C_{n+1}$ arises by multiplying $\Xi$ with the "left" square root matrix of $C_{n+1}^{-}$. The complexity remains the same (asymptotically, though QR decompositions cost more than matrix multiplications).

All in all, ODE filter steps preserve block-diagonal structure in the covariances. The expensive phases are the covariance extrapolation and correction in $O\left(d \nu^{3}\right)$ floating-point operations. The maximum memory demand is $O\left(d \nu^{2}\right)$ for the block diagonal covariances.

While it may seem restrictive at first to use only the diagonal of the Jacobian, Proposition 3 includes the EK0, one of the central ODE filters. The $O(d)$ complexity puts the EK0 and the diagonal EK1 into the complexity class of explicit Runge-Kutta methods. Usually, $\nu<12$ holds (Krämer and Hennig, 2020).

## 4 EK0 PRESERVES KRONECKER STRUCTURE

As hinted in Section 1, scalar or diagonal diffusion may be too restrictive in certain situations.
Example 4. Consider a spatio-temporal Gaussian process model $u(t, x) \sim \operatorname{GP}\left(0, \gamma^{2} k_{t} \otimes k_{x}\right)$, where $k_{t}$ is the covariance kernel that directly corresponds to an integrated Wiener process prior (Särkkä and Solin, 2019). Such a spatiotemporal model could be a useful prior distribution for applying an ODE solver to problems that are discretised PDEs, because $k_{x}$ encodes spatial dependency structures. Restricted to a spatial grid $\mathcal{X}:=\left\{x_{1}, \ldots, x_{G}\right\}, y:=u(t, \mathcal{X})$ satisfies the prior model in Eqs. (2) to (3) ${ }^{1}$, but with $\Gamma=\gamma^{2} k_{x}(\mathcal{X}, \mathcal{X})$ (Solin, 2016), which is usually dense.

### 4.1 Assumptions

Despite the lack of independence in Example 4, fast ODE solutions remain possible with the EK0. In the remainder of this section, let $\Gamma=\gamma^{2} \breve{\Gamma}$ for some matrix $\breve{\Gamma}$ and some scalar $\gamma$. Calibrating the scalar $\gamma$ allows preserving Kronecker structure in the system matrices that appear in an ODE filter step (Proposition 6 below). Tronarp et al. (2019) show how for $\Gamma=\gamma^{2} \breve{\Gamma}$, a timeconstant quasi-MLE $\hat{\gamma}$ arises in closed form and also, that the posterior covariances all look like $C_{n}=\gamma^{2} \breve{C}_{n}$ : calibration can happen entirely post-hoc.

Constraints The following statement about linear complexity of ODE filters is only valid under two constraints: one can ignore (i) the quadratic costs of multiplying the posterior covariances with the quasi-MLE, and (ii) the cubic costs of solving a linear system involving $\Gamma$. The system matrices $\Phi, \Sigma, C_{0}$ are all Kronecker products of a $\mathbb{R}^{d \times d}$ ("left") and a $\mathbb{R}^{\nu \times \nu}$ factor ("right"). The first constraint is thus avoided by scaling the "right" Kronecker factor of the covariances with $\gamma^{2}$ in $O\left(\nu^{2}\right)$. (ODE filters preserve Kronecker structure; see below.) The second one becomes the following assumption.
Assumption 5. Assume that the inverse of $\Gamma$ is readily available and cheap to apply; that is, the quantity $x^{\top} \Gamma^{-1} x$ can be computed in $O(d)$.

Naturally, Assumption 5 holds for diagonal or at least sufficiently sparse matrices $\Gamma$. There are also settings

[^1]

Figure 2: Runtime of a single ODE filter step: Run time (wall-clock) of a single step of ODE filter variations on the Lorenz96 problem (a) for increasing ODE dimension and $\nu=2,4,6$ (b-d). The traditional implementations cost $O\left(d^{3}\right)$ per step, the diagonal EK1 and diagonal EK0 are $O(d)$ per step, just like the Kronecker version of the EK0. The Kronecker EK0 is significantly faster than the diagonal version(s).
in which Assumption 5 holds even if $\Gamma$ is dense. For instance, if $\Gamma$ is the covariance of a Gauss-Markov random field, the sparsity structure in $\Gamma^{-1}$ implies adjacency of grid nodes (Lindgren et al., 2011; Sidén and Lindsten, 2020). In Example 4 with a spatial Matern kernel, for example, inverse Gram matrices can be approximated efficiently using the stochastic partial differential equation formulation (Lindgren et al., 2011).

### 4.2 Computational Complexity

Under Assumption 5, a single EK0 step costs $O(d)$ :
Proposition 6. Under Assumption 5, and if a timeconstant diffusion model $\Gamma=\gamma^{2} \breve{\Gamma}$ is calibrated via $\gamma$, a single step of the EKO costs $O\left(\nu^{3}+d \nu^{2}\right)$ floating point operations, and $O\left(d \nu+d^{2}+\nu^{2}\right)$ memory.

The proof parallels that of Proposition 3 (details are in Supplement C). It hinges on computing everything only in the "right" factor of each Kronecker matrix. The proposition can be extended to time-varying diffusion if one tracks $\gamma$ in the "right" Kronecker factor instead of the "left" one. Since this obfuscates the notation, we prove the claim in Supplement D. The quadratic $O\left(d^{2}\right)$ memory requirement is entirely due to the cost of storing $\Gamma$ - if $\Gamma$ or its inverse are banded matrices, for instance, it reduces to $O\left(d \nu+\nu^{2}\right)$.

## 5 EMPIRICAL EVALUATION

A Single ODE Filter Step We begin by evaluating the cost of a single step of the ODE filter variations on the Lorenz96 problem (Lorenz, 1996). This is a chaotic dynamical system and recommends itself for
the first experiment, as its dimension can be increased freely. Supplement E contains more detailed descriptions of all ODE models. We time a single ODE filter step for increasing ODE dimension $d$ and different solver orders $\nu \in\{2,4,6\}$. The results are depicted in Fig. 2. The traditional EK0 and EK1 become infeasible due to their cubic complexity in the dimension. The diagonal EK1 and the diagonal EK0 exhibit their $O(d)$ cost. The Kronecker EK0 is cheaper than the independence-based solvers. A step with the Kronecker EK0 takes $\sim 1$ second for a 16 million-dimensional ODE on a generic, consumer-level CPU. Altogether, Fig. 2 confirms Propositions 3 and 6.

A Full Simulation Next, we evaluate whether the performance gains for a single ODE filter step translate into a reduced overall runtime (including step-size adaptation and calibration) on a medium-dimensional problem: the Pleiades problem (Hairer et al., 1993). It describes the motion of seven stars in a plane and is commonly solved as a system of 28 first-order ODEs. The results are in Fig. 3. Pleiades reveals the increased efficiency of the ODE filters. The probabilistic solvers are as fast as Radau, only by a factor $\sim 10$ slower than SciPy's RK45 (Virtanen et al., 2020), but 100 times faster than their reference implementations. (It should be noted that the ODE filters use just-in-time compilation for some components, whereas SciPy does not.)

A High-Dimensional Setting To evaluate how well the improved efficiency translates to extremely high dimensions, we solve the discretised FitzHughNagumo PDE model on high spatial resolution (which translates to high dimensional ODEs). The results are in Fig. 4. The main takeaway is that ODEs with

Figure 3: Runtime efficiency of fast ODE filters: Run time per root mean-square error of the ODE filters (a) on the Pleiades problem (b). The figure also shows two reference ODE filters, EK0 and EK1 in the traditional implementation, and Scipy's RK45 (explicit) and Radau (implicit). On the 28-dimensional Pleiades problem, the improved implementation accelerates the ODE filter implementations significantly.

Figure 4: High-dimensional PDE discretisation: Runtime of ODE filters on the discretised FitzHughNagumo model for increasing ODE dimension (i.e. increasing spatial resolution) including calibration and adaptive time-steps. SciPy's DOP853 for reference. Simulating $\gg 10^{6}$-dimensional ODEs takes $\approx 3 h$.
millions of dimensions can be solved probabilistically within a realistic time frame (hours), which has not been possible before. GPUs improve the runtime for extremely high-dimensional problems $\left(d \gg 10^{5}\right)$.
a. Number of steps vs. stiffness

Figure 5: Stability: Number of steps taken by an ODE filter (a) for an increasingly stiff Van der Pol system (b). The diagonal EK1 is more stable than the EK0, but less stable than the EK1 (which is expected because it uses strictly less Jacobian information).

Stability Of The Diagonal EK1 How much do we lose by ignoring off-diagonal elements in the Jacobian? To evaluate the loss (or preservation) of stability against the $A$-stable EK1 (Tronarp et al., 2019), we solve the Van der Pol system (Guckenheimer, 1980). It includes a free parameter $\mu>0$, whose magnitude governs the stiffness of the problem: the larger $\mu$, the stiffer the problem, and for e.g. $\mu=10^{6}$, Van der Pol is a famously stiff equation. The results are in Fig. 5. We observe how the diagonal EK1 is less stable than the reference EK1 for increasing stiffness constant, but also that it is significantly more stable than the EK0, for instance. It is a success that the diagonal EK1 solves the van der Pol equation for large $\mu$.

## 6 CONCLUSION

For probabilistic ODE solvers to capitalize on their theoretical advantages, their computational cost has to come close to that of their non-probabilistic pointestimate counterparts (which benefit from decades of optimization). High-dimensional problems are one obstacle on this path, which we cleared here. We showed that independence assumptions in the underlying statespace model, or preservation of Kronecker structures, can bring the computational complexity of a large subset of known ODE filters close to non-probabilistic, explicit Runge-Kutta methods. As a result, probabilistic simulation of extremely large systems of ODEs is now possible, opening up opportunities to exploit the advantages of probabilistic ODE solvers on challenging real-world problems.

# Probabilistic ODE Solutions in Millions of Dimensions: Supplementary Materials 

## A SQUARE-ROOT IMPLEMENTATION OF PROBABILISTIC ODE SOLVERS

The following two sections detail the square-root implementation of the transitions underlying the probabilistic ODE solver. The whole section is a synopsis of the explanations by Krämer and Hennig (2020). See also the monograph by Grewal and Andrews (2014) for additional details.

## A. 1 Extrapolation

The extrapolation step

$$
\begin{equation*}
C_{n+1}^{-}=\Phi\left(h_{n}\right) C_{n} \Phi\left(h_{n}\right)^{\top}+\Sigma\left(h_{n}\right) \tag{26}
\end{equation*}
$$

does not lead to stability issues further down the line (i.e. in calibration/correction/smoothing steps) if carried out in square root form. Square-root form means that instead of tracking and propagating covariance matrices $C$, only square root matrices $C=\sqrt{C} \sqrt{C}^{\top}$ are used for extrapolation and correction steps without forming the full covariance.
This is possible by means of QR decompositions. The matrix square root $\sqrt{C_{n+1}^{-}}$arises from $\sqrt{C_{n}}$ through the QR decomposition of

$$
\begin{equation*}
Q\binom{R}{0} \leftarrow\binom{\sqrt{C_{n}} \Phi\left(h_{n}\right)^{\top}}{\sqrt{\Sigma\left(h_{n}\right)^{\top}}}, \quad \sqrt{C_{n+1}^{-}} \leftarrow R^{\top} \tag{27}
\end{equation*}
$$

because

$$
\begin{equation*}
R^{\top} R=\binom{R}{0}^{\top} Q^{\top} Q\binom{R}{0}=\binom{\sqrt{C_{n}} \Phi\left(h_{n}\right)^{\top}}{\sqrt{\Sigma\left(h_{n}\right)^{\top}}}^{\top}\binom{\sqrt{C_{n}} \Phi\left(h_{n}\right)^{\top}}{\sqrt{\Sigma\left(h_{n}\right)^{\top}}}=\Phi\left(h_{n}\right) C_{n} \Phi\left(h_{n}\right)^{\top}+\Sigma\left(h_{n}\right) \tag{28}
\end{equation*}
$$

QR decompositions of a rectangular matrix $M \in \mathbb{R}^{m \times n}, m>n \operatorname{costs} O\left(m n^{2}\right)$, which implies that the covariance square root correction costs $O\left(d^{3} \nu^{3}\right)$. The QR decomposition is unique up to orthogonal row-operations (e.g. multiplying with $\pm 1$ ). Probabilistic ODE solvers require only any square root matrix, so this equivalence relation can be safely ignored - they all imply the same covariance.

## A. 2 Correction

The correction follows a similar pattern. Recall the linearised observation model

$$
\begin{equation*}
\mathcal{I}(y) \approx \hat{\mathcal{I}}(y)=H y+b \tag{29}
\end{equation*}
$$

where $H$ contains the vector field information and the Jacobian information (potentially, depending on linearisation style). There are two ways of performing square root corrections: the conventional way, and the way that is tailored to probabilistic ODE solvers, which builds on Joseph form corrections.

Conventional Way Let $\sqrt{C^{-}}$be a matrix square root of the current extrapolated covariance (we drop the $n+1$ index for improved readability). Let $0_{n}$ be the $n \times n$ zero matrix, and $0_{n \times m}$ the $n \times m$ zero matrix. The heart of the square root correction is another QR decomposition of the matrix

$$
Q\left(\begin{array}{cc}
R_{11} & R_{12}  \tag{30}\\
0_{d(\nu+1) \times d} & R_{22}
\end{array}\right) \leftarrow\left(\begin{array}{cc}
{\sqrt{C^{-}}}^{\top} H^{\top} & {\sqrt{C^{-}}}^{\top} \\
0_{d(\nu+1) \times d} & 0_{d(\nu+1)}
\end{array}\right)
$$

with $R_{11} \in \mathbb{R}^{d \times d}, R_{12} \in \mathbb{R}^{d \times d(\nu+1)}$, and $R_{22} \in \mathbb{R}^{d(\nu+1) \times d(\nu+1)}$. The $R_{i j}$ matrices contain the relevant information about the covariance matrices involved in the correction:
$\diamond \sqrt{S}=R_{11}^{\top}$ is the matrix square root of the innovation covariance
$\diamond \sqrt{C}=R_{22}^{\top}$ is the matrix square root of the posterior covariance
$\diamond K=R_{12}\left(R_{11}\right)^{-1}$ is the Kalman gain and can be used to correct the mean
This QR decomposition costs $O\left(d^{3} \nu^{3}\right)$ again, but the matrix involved is larger than the stack of matrices in the extrapolation step (it has $d$ more columns), so for high dimensional problems, the increased overhead becomes significant. However, if only any square root matrix is desired, this step can be circumvented.

Joseph Way Again, let $\sqrt{C^{-}}$be the square root matrix of the current extrapolated covariance which results from the extrapolation step in square root form. Next, the full covariance is assembled (which goes against the usual grain of avoiding full covariance matrices, but in the present case does the job) as $C^{-}=\sqrt{C^{-}} \sqrt{C^{-}}{ }^{\top}$. Since in the probabilistic solver, $C^{-}$is either a Kronecker matrix $I_{d} \otimes \breve{C}^{-}$or a block diagonal matrix blockdiag $\left(\left(C^{-}\right)^{1}, \ldots,\left(C^{-}\right)^{d}\right)$, this is sufficiently cheap. The innovation covariance itself then becomes

$$
\begin{align*}
S & =H C^{-} H^{\top}  \tag{31a}\\
& =\left(E_{1}-F_{x} E_{0}\right) C^{-}\left(E_{1}-F_{x} E_{0}\right)^{\top}  \tag{31b}\\
& =E_{1} C^{-} E_{1}^{\top}-F_{x} E_{0} C^{-} E_{1}^{\top}-E_{1} C^{-} E_{0}^{\top} F_{x}^{\top}+F_{x} E_{0} C^{-} E_{0}^{\top} F_{x}^{\top} \tag{31c}
\end{align*}
$$

which can be computed rather efficiently because $E_{i} C^{-} E_{j}^{\top}$ only involves accessing elements, not matrix multiplication. The only non-negligible cost here is multiplication with the Jacobian of the ODE vector field (which is often sparse in high-dimensional problems). Then, the Kalman gain

$$
\begin{equation*}
K=C^{-} H^{\top} S^{-1} \tag{32}
\end{equation*}
$$

can be computed from $S$ which implies that the covariance correction reduces to

$$
\begin{equation*}
\sqrt{C}=(I-K H) \sqrt{C^{-}} \tag{33}
\end{equation*}
$$

which is the "left half" of the Joseph correction. The resulting matrix is square, and a matrix square root of the posterior covariance, but not triangular thus no valid Cholesky factor. If the sole purpose of the square root matrices is improved numerical stability, generic square root matrices suffice.

## B INDEPENDENCE AND FAST ODE FILTERS FOR TIME-CONSTANT DIFFUSION

A similar result to Proposition 2 can be formulated for vector-valued, time-constant diffusion models.
Proposition B1. Under Assumption 1 and for diagonal $F_{y}$, a quasi-maximum likelihood estimate (MLE) for a vector-valued, time-constant diffusion model $\Gamma=\operatorname{diag}\left(\left(\gamma^{1}\right)^{2}, \ldots,\left(\gamma^{d}\right)^{2}\right)$ is given by the estimator

$$
\begin{equation*}
\left(\hat{\gamma}^{i}\right)^{2}:=\frac{1}{N} \sum_{i=1}^{N} \frac{\left(z_{n}^{i}\right)^{2}}{\left[S_{n}\right]_{i i}}, \quad i=1, \ldots, d \tag{34}
\end{equation*}
$$

where $S_{n}:=H\left(t_{n}\right) \Sigma\left(h_{n}\right) H\left(t_{n}\right)^{\top}$ is the diagonal covariance matrix of the measurement $Z_{n}$ (recall Section 2.2).

Proof. The proof is structured as follows. First, we show that an initial covariance

$$
\begin{equation*}
C_{0}=\operatorname{blockdiag}\left(\left(\gamma^{1}\right)^{2} \breve{C}_{0}, \ldots,\left(\gamma^{d}\right)^{2} \breve{C}_{0}\right) \tag{35}
\end{equation*}
$$

implies covariances

$$
\begin{align*}
C_{n}^{-} & =\operatorname{blockdiag}\left(\left(\gamma^{1}\right)^{2}\left(C_{n}^{1}\right)^{-}, \ldots,\left(\gamma^{d}\right)^{2}\left(C_{n}^{d}\right)^{-}\right)  \tag{36a}\\
C_{n} & =\operatorname{blockdiag}\left(\left(\gamma^{1}\right)^{2} C_{n}^{1}, \ldots,\left(\gamma^{d}\right)^{2} C_{n}^{d}\right)  \tag{36b}\\
S_{n} & =\operatorname{diag}\left(\left(\gamma^{1}\right)^{2} s_{n}^{1}, \ldots,\left(\gamma^{d}\right)^{2} s_{n}^{d}\right) \tag{36c}
\end{align*}
$$

Then, for measurement covariances $S_{n}$ of such form, we can compute the (quasi) maximum likelihood estimate $\hat{\Gamma}$. Because every covariance depends multiplicatively on $\gamma$, calibration can happen entirely post-hoc.

Block-Wise Scalar Diffusion Recall from Section 2.1 that the transition matrix and the process noise covariance are of the form $\Phi\left(h_{n}\right)=I_{d} \otimes \breve{\Phi}\left(h_{n}\right)$ and $\Sigma\left(h_{n}\right)=\Gamma \otimes \breve{\Sigma}\left(h_{n}\right)$. Thus, for a diagonal diffusion $\Gamma=\operatorname{diag}\left(\left(\gamma^{1}\right)^{2}, \ldots,\left(\gamma^{d}\right)^{2}\right)$, both $\Phi\left(h_{n}\right)$ and $\Sigma\left(h_{n}\right)$ are block diagonal. Assuming a block diagonal covariance matrix that depends multiplicatively on $\gamma$,

$$
\begin{equation*}
C_{n-1}=\operatorname{blockdiag}\left(\left(\gamma^{1}\right)^{2} C_{n-1}^{1}, \ldots,\left(\gamma^{d}\right)^{2} C_{n-1}^{d}\right) \tag{37}
\end{equation*}
$$

the extrapolated covariance is also of the form

$$
\begin{align*}
C_{n}^{-} & =\operatorname{blockdiag}\left(\left(\gamma^{1}\right)^{2}\left(C_{n}^{1}\right)^{-}, \ldots,\left(\gamma^{d}\right)^{2}\left(C_{n}^{d}\right)^{-}\right)  \tag{38a}\\
\left(C_{n}^{i}\right)^{-} & :=\breve{\Phi}\left(h_{n}\right) C_{n-1}^{i} \breve{\Phi}\left(h_{n}\right)^{\top}+\breve{\Sigma}\left(h_{n}\right), \quad i=1, \ldots, d \tag{38b}
\end{align*}
$$

The diagonal Jacobian $F_{y}$ implies a block diagonal linearisation matrix

$$
\begin{align*}
& H_{n}=E_{1}-F_{y} E_{0}=\operatorname{blockdiag}\left(H_{n}^{1}, \ldots, H_{n}^{d}\right)  \tag{39a}\\
& H_{n}^{i}:=e_{1}-\left[F_{y}\right]_{i, i} e_{0}, \quad i=1, \ldots, d \tag{39b}
\end{align*}
$$

The measurement covariance $S_{n}$ is therefore given by a diagonal matrix and depends multiplicatively on $\gamma$, as

$$
\begin{align*}
& S_{n}=H_{n} C_{n}^{-} H_{n}^{\top}=\operatorname{diag}\left(\left(\gamma^{1}\right)^{2} s_{n}^{1}, \ldots,\left(\gamma^{d}\right)^{2} s_{n}^{d}\right)  \tag{40a}\\
& s_{n}^{i}:=H_{n}^{i}\left(C_{n}^{i}\right)^{-}\left(H_{n}^{i}\right)^{\top}, \quad i=1, \ldots, d . \tag{40b}
\end{align*}
$$

This implies a block diagonal Kalman gain

$$
\begin{align*}
& \Xi_{n}=I-C_{n}^{-} H\left(t_{n}\right)^{\top} S_{n}^{-1} H\left(t_{n}\right)=\text { blockdiag }\left(\Xi_{n}^{1}, \ldots \Xi_{n}^{d}\right),  \tag{41a}\\
& \Xi_{n}^{i}:=I_{\nu+1}-\left(C_{n}^{-}\right)^{i}\left(H_{n}^{i}\right)^{\top} H_{n}^{i} / s_{n}^{i} \quad i=1, \ldots, d . \tag{41~b}
\end{align*}
$$

Finally, we obtain the corrected covariance

$$
\begin{align*}
& C_{n}=\text { blockdiag }\left(\left(\gamma^{1}\right)^{2} C_{n}^{1}, \ldots,\left(\gamma^{d}\right)^{2} C_{n}^{d}\right)  \tag{42a}\\
& C_{n}^{i}:=\Xi_{n}^{i}\left(C_{n}^{i}\right)^{-}\left(\Xi_{n}^{i}\right)^{\top} \quad i=1, \ldots, d \tag{42~b}
\end{align*}
$$

This concludes the first part of the proof.
Computing The Quasi-MLE It is left to compute the (quasi) MLE $\hat{\Gamma}=\operatorname{diag}\left(\left(\hat{\gamma}^{1}\right)^{2}, \ldots,\left(\hat{\gamma}^{d}\right)^{2}\right)$ by maximizing the $\log$-likelihood $\log p\left(z_{1: N}\right)=\log \prod_{n=1}^{N} \mathcal{N}\left(0 ; z_{n}, S_{n}\right)$. Since $S_{n}=\operatorname{diag}\left(\left(\gamma^{1}\right)^{2} s_{n}^{1}, \ldots,\left(\gamma^{d}\right)^{2} s_{n}^{d}\right)$ is a diagonal matrix, we obtain

$$
\begin{align*}
\hat{\Gamma} & =\underset{\Gamma}{\arg \max } \sum_{n=1}^{N} \log \mathcal{N}\left(0 ; z_{n}, S_{n}\right)  \tag{43a}\\
& =\underset{\Gamma}{\arg \max } \sum_{i=1}^{d}\left(-\frac{N \log \left(\hat{\gamma}^{i}\right)^{2}}{2}-\sum_{n=1}^{N} \frac{\left(z_{n}\right)_{d}^{2}}{2 s_{n}^{i}\left(\hat{\gamma}^{i}\right)^{2}}\right) \tag{43~b}
\end{align*}
$$

By taking the derivative and setting it to zero, we obtain the quasi-MLE from Eq. (34).

## C PROOF OF Proposition 6

Proof. Let $Y_{n} \sim \mathcal{N}\left(m_{n}, C_{n}\right)$. Assume $C_{n}=\Gamma \otimes \breve{C}_{n}$ which is no loss of generality, because such a Kronecker structure is preserved through the ODE filter step as shown below.
(i) Extrapolate mean: The mean extrapolation $\operatorname{costs} O\left(d \nu^{2}\right)$ like in the proof of Proposition 3.
(ii) Evaluate the $O D E$ : Evaluation of $H$ and $b$ is essentially free - recall that we only consider the EK0 in this setting, which uses the projection $H\left(t_{n}\right)=E_{1}$. Matrix multiplication with $H$ consists of a projection, which costs $O(1)$.
(iii) Calibrate: Calibration of a time-constant $\gamma^{2}$ costs $O(d)$ under Assumption 5.
(iv) Extrapolate covariance: In the time-constant diffusion model, $\Sigma\left(h_{n}\right)$ and $C_{n}$ are both Kronecker matrices and share the left Kronecker factor: $\Gamma$. Thus, the extrapolation of the covariance can be carried out "in the right Kronecker factor", which costs $O\left(\nu^{3}\right)$ in traditional as well as square root implementation. Denote the extrapolated covariance by $C_{n+1}^{-}:=\Gamma \otimes \breve{C}_{n+1}^{-}$.
(v) Measure: Recall $H\left(t_{n}\right)=E_{1}=I \otimes e_{1}$. The mean of the measured random variable $Z_{n} \sim \mathcal{N}\left(z_{n}, S_{n}\right)$ comes at negligible cost. The covariance

$$
\begin{equation*}
S_{n+1}=H\left(t_{n+1}\right) C_{n+1}^{-} H\left(t_{n+1}\right)^{\top}=\Gamma \otimes\left[e_{1} \breve{C}_{n+1}^{-} e_{1}^{\top}\right] \tag{44}
\end{equation*}
$$

requires a single element in $\breve{C}_{n+1}^{-}$. The Kalman gain

$$
\begin{equation*}
K:=C_{n+1}^{-} H\left(t_{n+1}\right)^{\top} S_{n+1}^{\top}=I \otimes \breve{K} \tag{45}
\end{equation*}
$$

with $\breve{K}:=e_{1} \breve{C}_{n+1}^{-} /\left[e_{1} \breve{C}_{n+1}^{-} e_{1}^{\top}\right]$ involves dividing the first row of $\breve{C}_{n+1}^{-}$by a scalar. Its cost is $O(\nu+1)$.
(v) Correct mean and covariance: The mean is corrected in $O\left(d \nu^{2}\right)$ as in the proof of Proposition 3. Due to the Kronecker structure in $K$, the "left" Kronecker factor of $C_{n+1}$ must be $\Gamma$ again. Therefore, we need to correct only the "right" Kronecker factor in $O\left(\nu^{3}\right)$.
All in all, under the assumption of cheap calibration, a single step with the EK0 costs $O\left(d \nu^{2}\right)$ and the expensive steps are (as before) the covariance extrapolation and the covariance correction. The total memory costs are the requirements of storing $\Gamma$, the mean(s) in $O(\nu d)$, and the "right" Kronecker factor(s) in $O\left(\nu^{2}\right)$.

## D KRONECKER STRUCTURE AND FAST ODE FILTERS FOR TIME-VARYING DIFFUSION

In the following we extend the results of Proposition 6 to time-varying diffusion models.
Proposition D1. Under Assumption 5, and if a time-varying diffusion model $\Gamma_{n}=\gamma_{n}^{2} \breve{\Gamma}$ is calibrated via $\gamma_{n}$, a single step of the EKO costs $O\left(\nu^{3}+d \nu^{2}\right)$ floating point operations, and $O\left(d \nu+d^{2}+\nu^{2}\right)$ memory.

Proof. The proof of Proposition 6 shown in Supplement C depends on the specific time-fixed diffusion model only in the calibration (iii) and the extrapolation of the covariance (iv). In the following, we discuss these two steps for a time-varying diffusion $\Gamma_{n}=\gamma_{n}^{2} \stackrel{\breve{\Gamma}}{ }$. We show that Kronecker structure is preserved and we obtain the same complexities as in Proposition 6.
(iii) Calibrate: Calibration of a time-varying $\gamma_{n+1}^{2}$ is done with

$$
\begin{align*}
\hat{\gamma}_{n+1}^{2}: & =\frac{1}{d} z_{n+1}^{\top}\left[H\left(t_{n+1}\right) \Sigma\left(h_{n+1}\right) H\left(t_{n+1}\right)^{\top}\right]^{-1} z_{n+1}  \tag{46a}\\
& =\frac{1}{d} z_{n+1}^{\top}\left(\breve{\Gamma}_{n+1} \cdot\left[\breve{\Sigma}_{n+1}^{-}\right]_{11}\right)^{-1} z_{n+1}  \tag{46b}\\
& =\frac{1}{d} z_{n+1}^{\top}\left(\breve{\Gamma}_{n+1}\right)^{-1} z_{n+1} /\left[\breve{\Sigma}_{n+1}^{-}\right]_{11} \tag{46c}
\end{align*}
$$

where we used that $H\left(t_{n}\right)=I \otimes e_{1}$. With Assumption 5, this computation costs $O(d)$.
(iv) Extrapolate covariance: Assume a covariance of the form $C_{n}=\left(\gamma_{n}^{2} \breve{\Gamma}\right) \otimes \breve{C}_{n}$. Since scalars can be moved between the Kronecker factors, the covariance matrix can be written with the diffusion matrix $\Gamma_{n+1}=\gamma_{n+1}^{2} \breve{\Gamma}$, as

$$
\begin{equation*}
C_{n}=\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes\left(\frac{\gamma_{n}^{2}}{\gamma_{n+1}^{2}} \breve{C}_{n}\right) \tag{47}
\end{equation*}
$$

Then, since $\Sigma_{n+1}=\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes \breve{\Sigma}_{n+1}$, the prediction step can be written as

$$
\begin{align*}
C_{n+1}^{-} & =\Phi\left(h_{n+1}\right) C_{n} \Phi\left(h_{n+1}\right)^{\top}+\Sigma\left(h_{n+1}\right)  \tag{48a}\\
& =\left(I_{d} \otimes \breve{\Phi}\left(h_{n+1}\right)\right)\left(\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes\left(\frac{\gamma_{n}^{2}}{\gamma_{n+1}^{2}} \breve{C}_{n}\right)\right)\left(I_{d} \otimes \breve{\Phi}\left(h_{n+1}\right)\right)^{\top}+\left(\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes \breve{\Sigma}_{n+1}\right)  \tag{48b}\\
& =\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes\left(\frac{\gamma_{n}^{2}}{\gamma_{n+1}^{2}} \breve{\Phi}\left(h_{n+1}\right) \breve{C}_{n} \breve{\Phi}\left(h_{n+1}\right)^{\top}+\breve{\Sigma}_{n+1}\right)  \tag{48c}\\
& =:\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes \breve{C}_{n+1}^{-} . \tag{48~d}
\end{align*}
$$

With a Kalman gain of the form $K=I \otimes \breve{K}$, the corrected covariance can be written as $C_{n+1}=\left(\gamma_{n+1}^{2} \breve{\Gamma}\right) \otimes \breve{C}_{n+1}$, thus confirming our assumption on the Kronecker structure of covariance matrices. Since all matrix multiplications happen only "in the right Kronecker factor", extrapolating the covariance costs $O\left(\nu^{3}\right)$.
All other parts of the proof can be reproduced as in Supplement $C$ to obtain the specified complexities.

## E ODE PROBLEMS

## E. 1 Lorenz96

The Lorenz96 model describes a chaotic dynamical system for which the dimension can be chosen freely (Lorenz, 1996). It is given by a system of $N \geq 4$ ODEs

$$
\begin{align*}
\dot{y}_{1} & =\left(y_{2}-y_{N-1}\right) y_{N}-y_{1}+F,  \tag{49a}\\
\dot{y}_{2} & =\left(y_{3}-y_{N}\right) y_{1}-y_{2}+F,  \tag{49b}\\
\dot{y}_{i} & =\left(y_{i+1}-y_{i-2}\right) y_{i-1}-y_{i}+F \quad i=3, \ldots, N-1,  \tag{49c}\\
\dot{y}_{N} & =\left(y_{1}-y_{N-2}\right) y_{N-1}-y_{N}+F, \tag{49d}
\end{align*}
$$

with forcing term $F=8$, initial values $y_{1}(0)=F+0.01$ and $y_{>1}(0)=F$, and time span $t \in[0,30]$.

## E. 2 Pleiades

The Pleiades system describes the motion of seven stars in a plane, with coordinates $\left(x_{i}, y_{i}\right)$ and masses $m_{i}=i$, $i=1, \ldots, 7$ (Hairer et al., 1993, Section II.10). It can be described with a system of 28 ODEs

$$
\begin{align*}
\dot{x}_{i} & =v_{i}  \tag{50a}\\
\dot{y}_{i} & =w_{i}  \tag{50b}\\
\dot{v}_{i} & =\sum_{j \neq i} m_{j}\left(x_{j}-x_{i}\right) / r_{i j}  \tag{50c}\\
\dot{w}_{i} & =\sum_{j \neq i} m_{j}\left(y_{j}-y_{i}\right) / r_{i j} \tag{50~d}
\end{align*}
$$

where $r_{i j}=\left(\left(x_{i}-x_{j}\right)^{2}+\left(y_{i}-y_{j}\right)^{2}\right)^{3 / 2}$, for $i, j=1, \ldots, 7$. It is commonly solved on the time span $t \in[0,3]$ and with initial locations

$$
\begin{align*}
x(0) & =[3,3,-1,-3,2,-2,2]  \tag{51a}\\
y(0) & =[3,-3,2,0,0,-4,4]  \tag{51b}\\
v(0) & =[0,0,0,0,0,1.75,-1.5]  \tag{51c}\\
w(0) & =[0,0,0,-1.25,1,0,0] \tag{51~d}
\end{align*}
$$

## E. 3 FitzHugh-Nagumo PDE

Let $\Delta=\sum_{i=1}^{d} \frac{\partial^{2}}{\partial x_{i}^{2}}$ be the Laplacian. The FitzHugh-Nagumo partial differential equation (PDE) is (Ambrosio and Françoise, 2009)

$$
\begin{align*}
\frac{\partial}{\partial t} u(t, x) & =a \Delta u(t, x)+u(t, x)-u(t, x)^{3}-v(t, x)+k  \tag{52a}\\
\frac{\partial}{\partial t} v(t, x) & =\frac{1}{\tau}(b \Delta v(t, x)+u(t, x)-v(t, x)) \tag{52b}
\end{align*}
$$

for $x \in[0,1] \times[0,1] \subseteq \mathbb{R}^{2}$, some parameters $a, b, k, \tau$, and initial values $u\left(t_{0}, x\right)=h_{0}(x), v\left(t_{0}, x\right)=h_{1}(x)$. In our experiments, we chose $a=208 \cdot 10^{-4}, b=5 \cdot 10^{-3}, k=-5 \cdot 10^{-3}, \tau=0.1$. As initial values, we used random samples from the uniform distribution on $(0,1)$. We solve it from $t_{0}=0$ to $t_{\max }=20$. To turn the PDE into a system of ODEs, we discretised the Laplacian with central, second-order finite differences schemes on a uniform grid. The mesh size of the grid determines the number of grid points, which controls the dimension of the ODE problem.

## E. 4 Van der Pol

The Van der Pol system is often employed to evaluate the stability of stiff ODE solvers (Wanner and Hairer, 1996). It is given by a system of ODEs

$$
\begin{equation*}
\dot{y_{1}}(t)=y_{2}(t), \quad \dot{y_{2}}(t)=\mu\left(\left(1-y_{1}^{2}(t)\right) y_{2}(t)-y_{1}(t)\right), \tag{53}
\end{equation*}
$$

with stiffness constant $\mu>0$, time span $t \in[0,6.3]$, and initial value $y(0)=[2,0]$.
