Abstract

We propose a modular extension of backpropagation for the computation of block-diagonal approximations to various curvature matrices of the training objective (in particular, the Hessian, generalized Gauss-Newton, and positive-curvature Hessian). The approach reduces the otherwise tedious manual derivation of these matrices into local modules, and is easy to integrate into existing machine learning libraries. Moreover, we develop a compact notation derived from matrix differential calculus. We outline different strategies applicable to our method. They subsume recently-proposed block-diagonal approximations as special cases, and are extended to convolutional neural networks in this work.

1 Introduction

Gradient backpropagation is the central computational operation of contemporary deep learning. Its modular structure allows easy extension across network architectures, and thus automatic computation of gradients given the computational graph of the forward pass (for a review, see Baydin et al., 2018). But optimization using only the first-order information of the objective’s gradient can be unstable and slow, due to “vanishing” or “exploding” behaviour of the gradient. Incorporating curvature, second-order methods can avoid such scaling issues and converge in fewer iterations. Such methods locally approximate the objective function E by a quadratic $E(x) + \delta x^\top (x_* - x) + \frac{1}{2}(x_* - x)^\top C(x_* - x)$ around the current location x , using the gradient

$\delta x = \partial E / \partial x$ and a positive semi-definite (PSD) curvature matrix C — the Hessian of E or approximations thereof. The quadratic is minimized by

$$x_* = x + \Delta x \quad \text{with} \quad \Delta x = -C^{-1} \delta x. \quad (1)$$

Computing the update step requires that the $C \Delta x = -\delta x$ linear system be solved. To accomplish this task, providing a matrix-vector multiplication with the curvature matrix C is sufficient.

Approaches to second-order optimization: For some curvature matrices, exact multiplication can be performed at the cost of one backward pass by automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). This *matrix-free* formulation can then be leveraged to solve (1) using iterative solvers such as the method of conjugate gradients (CG) (Martens, 2010). However, since this linear solver can still require multiple iterations, the increased per-iteration progress of the resulting optimizer might be compensated by increased computational cost. Recently, a parallel version of Hessian-free optimization was proposed in (Zhang et al., 2017), which only considers the content of Hessian sub-blocks along the diagonal. Reducing the Hessian to a block diagonal allows for parallelization, tends to lower the required number of CG iterations, and seems to improve the optimizer’s performance.

There have also been attempts to compute parts of the Hessian in an iterative fashion (Mizutani and Dreyfus, 2008). Storing these constituents efficiently often requires an involved manual analysis of the Hessian’s structure, leveraging its outer-product form in many scenarios (Naumov, 2017; Bakker et al., 2018). Recent works developed different block-diagonal approximations (BDA) of curvature matrices that provide fast multiplication (Martens and Grosse, 2015; Grosse and Martens, 2016; Botev et al., 2017; Chen et al., 2018).

These works have repeatedly shown that, empirically, second-order information can improve the training of

Figure 1: Standard feedforward network architecture, i.e. the repetition of affine transformations parameterized by $\theta^{(i)} = (W^{(i)}, b^{(i)})$ followed by elementwise activations. Arrows from left to right and vice versa indicate the data flow during forward pass and gradient backpropagation, respectively.

deep learning problems. Perhaps the most important practical hurdle to the adoption of second-order optimizers is that they tend to be tedious to integrate in existing machine learning frameworks because they require manual implementations. As efficient automated implementations have arguably been more important for the wide-spread use of deep learning than many conceptual advances, we aim to develop a framework that makes computation of Hessian approximations about as easy and automated as gradient backpropagation.

Contribution: This paper introduces a modular formalism for the computation of block-diagonal approximations of Hessian and curvature matrices, to various block resolutions, for feedforward neural networks. The framework unifies previous approaches in a form that, similar to gradient backpropagation, reduces implementation and analysis to local modules. Following the design pattern of gradient backprop also has the advantage that this formalism can readily be integrated into existing machine learning libraries, and flexibly modified for different block groupings and approximations.

The framework consists of three principal parts:

1. a modular formulation for *exact* computation of Hessian block diagonals of feedforward neural nets. We achieve a clear presentation by leveraging the notation of matrix differential calculus (Magnus and Neudecker, 1999).
2. projections onto the positive semi-definite cone by eliminating sources of concavity.
3. backpropagation strategies to obtain (i) exact curvature matrix-vector products (with previously inaccessible BDAs of the Hessian) and (ii) further approximated multiplication routines that save computations by evaluating the matrix representations of intermediate quantities once, at the cost of additional memory consumption.

The first two contributions can be understood as an explicit formulation of well-known tricks for fast mul-

tiplication by curvature matrices using automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). However, we also address a new class of curvature matrices, the positive-curvature Hessian (PCH) introduced in Chen et al. (2018). Our solutions to the latter two points are generalizations of previous works (Botev et al., 2017; Chen et al., 2018) to the fully modular case, which become accessible due to the first contribution. They represent additional modifications to make the scheme computationally tractable and obtain curvature approximations with desirable properties for optimization.

2 Notation

We consider feedforward neural networks composed of ℓ modules $f^{(i)}, i = 1, \dots, \ell$, which can be represented as a computational graph mapping the input $z^{(0)} = x$ to the output $z^{(\ell)}$ (Figure 1). A module $f^{(i)}$ receives the parental output $z^{(i-1)}$, applies an operation involving the network parameters $\theta^{(i)}$, and sends the output $z^{(i)}$ to its child. Thus, $f^{(i)}$ is of the form $z^{(i)} = f^{(i)}(z^{(i-1)}, \theta^{(i)})$. Typical choices include elementwise nonlinear activation without any parameters and affine transformations $z^{(i)} = W^{(i)}z^{(i-1)} + b^{(i)}$ with parameters given by the weights $W^{(i)}$ and the bias $b^{(i)}$. Affine and activation modules are usually considered as a single conceptual unit, one *layer* of the network. However, for backpropagation of derivatives it is simpler to consider them separately as two *modules*.

Given the network output $z^{(\ell)}(x, \theta^{(1, \dots, \ell)})$ of a datum x with label y , the goal is to minimize the expected risk of the loss function $E(z^{(\ell)}, y)$. Under the framework of empirical risk minimization, the parameters are tuned to optimize the loss on the training set $Q = \{(x, y)_{i=1}^N\}$,

$$\min_{\theta^{(1, \dots, \ell)}} \frac{1}{|Q|} \sum_{(x, y) \in Q} E(z^{(\ell)}(x), y). \quad (2)$$

In practice, the objective is typically further approximated stochastically by drawing a mini-batch $B \subset Q$ from the training set. We will treat both scenarios

without further distinction, since the structure relevant to our purposes is that Equation (2) is an average of terms depending on individual data points. Quantities for optimization, be it gradients or second derivatives of the loss with respect to the network parameters, can be processed in parallel, then averaged.

3 Main contribution

First-order auto-differentiation for a custom module requires the definition of only two local operations, *forward* and *backward*, whose outputs are propagated along the computation graph. This modularity facilitates the extension of gradient backpropagation by new operations, which can then be used to build networks by composition. To illustrate the principle, we consider a single module from the network of Figure 1, depicted in Figure 2, in this section. The forward pass $f(x, \theta)$ maps the input x to the output z by means of the module parameters θ (to simplify notation, we drop layer indices). All quantities are assumed to be vector-shaped (tensor-valued quantities can be vectorized, see Section A of the Supplements). Optimization requires the gradient of the loss function with respect to the parameters, $\partial E(\theta)/\partial \theta = \delta \theta$. We will use the shorthand

$$\delta \cdot = \frac{\partial E(\cdot)}{\partial \text{vec}(\cdot)}. \quad (3)$$

During gradient backpropagation the module receives the loss gradient with respect to its output, δz , from its child. The backward operation computes gradients with respect to the module parameters and input, $\delta \theta$ and δx from δz . Backpropagation continues by sending the gradient with respect to the module’s input to its parent, which proceeds in the same way (see Figure 1). By the chain rule, gradients with respect to an element of the module’s input can be computed as $\delta x_i = \sum_j (\partial z_j / \partial x_i) \delta z_j$. The vectorized version is compactly written in terms of the Jacobian matrix $Dz(x) = \partial z(x) / \partial x^\top$, which contains all partial derivatives of z with respect to x . The arrangement of partial derivatives is such that $[Dz(x)]_{j,i} = \partial z_j(x) / \partial x_i$, i.e.

$$\delta x = [Dz(x)]^\top \delta z. \quad (4)$$

Analogously, the parameter gradients are given by $\delta \theta_i = \sum_j \frac{\partial z_j}{\partial \theta_i} \delta z_j$, i.e. $\delta \theta = [Dz(\theta)]^\top \delta z$, which reflects the

Figure 2: Forward pass, gradient backpropagation, and Hessian backpropagation for a single module. Arrows from left to right indicate the data flow in the forward pass $z = f(x, \theta)$, while the opposite orientation indicates the gradient backpropagation by Equation (4). We suggest to extend this by the backpropagation of the Hessian as indicated by Equation (7).

symmetry of both x and θ acting as input to the module. Implementing gradient backpropagation thus requires multiplications by (transposed) Jacobians.

We can apply the chain rule a second time to obtain expressions for second-order partial derivatives of the loss function E with respect to elements of x or θ ,

$$\begin{aligned} \frac{\partial^2 E(x)}{\partial x_i \partial x_j} &= \frac{\partial}{\partial x_j} \left(\sum_k \frac{\partial z_k}{\partial x_i} \delta z_k \right) \\ &= \sum_{k,l} \frac{\partial z_k}{\partial x_i} \frac{\partial^2 E(z)}{\partial z_k \partial z_l} \frac{\partial z_l}{\partial x_j} + \sum_k \frac{\partial^2 z_k}{\partial x_i \partial x_j} \delta z_k, \end{aligned} \quad (5)$$

by means of $\partial / \partial x_j = \sum_l (\partial z_l / \partial x_j) \partial / \partial z_l$ and the product rule. The first term of Equation (5) propagates curvature information of the output further back, while the second term introduces second-order effects of the module itself. Using the Hessian matrix $\text{HE}(x) = \partial^2 E(x) / (\partial x^\top \partial x)$ of a scalar function with respect to a vector-shaped quantity x , the Hessian of the loss function will be abbreviated by

$$\text{HE}(\cdot) = \mathcal{H} \cdot = \frac{\partial^2 E(\cdot)}{\partial \text{vec}(\cdot)^\top \partial \text{vec}(\cdot)}, \quad (6)$$

which results in the matrix version of Equation (5),

$$\mathcal{H}x = [Dz(x)]^\top \mathcal{H}z [Dz(x)] + \sum_k [\text{Hz}_k(x)] \delta z_k. \quad (7)$$

Note that the second-order effect introduced by the module itself via $\text{Hz}_k(x)$ vanishes if $f_k(x, \theta)$ is linear in x . Because the layer parameters θ can be regarded as inputs to the layer, they are treated in exactly the same way, replacing x by θ in the above expression.

Equation (7) is the central functional expression herein, and will be referred to as the *Hessian backpropagation (HBP) equation*. Our suggested extension of gradient backpropagation is to also send the Hessian $\mathcal{H}z$ back through the graph. To do so, existing modules have to be extended by the HBP equation: *Given the Hessian $\mathcal{H}z$ of the loss with respect to all module outputs, an extended module has to extract the Hessians $\mathcal{H}\theta, \mathcal{H}x$ by means of Equation (7), and forward the Hessian with respect to its input $\mathcal{H}x$ to the parent module which proceeds likewise.* In this way, backprop of gradients

Figure 3: Extension of backprop to Hessians. It yields diagonal blocks of the full parameter Hessian.

can be extended to compute curvature information in modules. This corresponds to BDAs of the Hessian that ignore second-order partial derivatives of parameters in different modules. Figure 3 shows the data flow. The computations required in Equation (7) depend only on *local quantities* that are, mostly, already being computed during gradient backpropagation.¹

Before we proceed, we highlight the following aspects:

- The BDA of the Hessian need not be PSD. But our scheme can be modified to provide PSD curvature matrices by projection onto the positive semi-definite cone (see Subsection 3.1).
- Instead of evaluating all matrices during backpropagation, we can define matrix-vector products recursively. This yields exact curvature matrix products with the block diagonals of the Hessian, the generalized Gauss-Newton (GGN) matrix and the PCH. Products with the first two matrices can also be obtained by use of automatic differentiation (Pearlmutter, 1994; Schraudolph, 2002). We also get access to the PCH which, in contrast to the GGN, considers curvature information introduced by the network (see Subsection 3.1).² For standard neural networks, only second derivatives of nonlinear activations have to be stored compared to gradient backpropagation.
- There are approaches (Botev et al., 2017; Chen et al., 2018) that propagate matrix representations back through the graph in order to save repeated computations in the curvature matrix-vector product. The size of the matrices $\mathcal{H}z^{(i)}$ passed between layer $i+1$ and i scales quadratically in the number of output features of layer i . For convolutional

¹ By Faà di Bruno’s formula (Johnson, 2002) higher-order derivatives of function compositions are expressed recursively in terms of the composites’ lower-order derivatives. Recycling these quantities can give significant speedup compared to repeatedly applying first-order auto-differentiation, which represents one key aspect of our work.

²Implementations of HBP for exact matrix-vector products can reuse multiplication by the (transposed) Jacobian provided by many machine learning libraries. The second term of (7) needs special treatment though.

layers and in case of batched input data, the dimension of these quantities exceeds computational budgets. In line with previous schemes (Botev et al., 2017; Chen et al., 2018), we introduce additional approximations for batch learning in Subsection 3.2. A connection to existing schemes is drawn in the Supplements B.4.

HBP can easily be integrated into current machine learning libraries, so that BDAs of curvature information can be provided automatically for novel or existing second-order optimization methods. Such methods have repeatedly been shown to be competitive with first-order methods (Martens and Grosse, 2015; Grosse and Martens, 2016; Botev et al., 2017; Zhang et al., 2017; Chen et al., 2018).

Relationship to matrix differential calculus:

To some extent, this paper is a re-formulation of earlier results (Martens and Grosse, 2015; Botev et al., 2017; Chen et al., 2018) in the framework of matrix differential calculus (Magnus and Neudecker, 1999), leveraged to achieve a new level of modularity. Matrix differential calculus is a set of notational rules that allow a concise construction of derivatives without the heavy use of indices. Equation (7) is a special case of the matrix chain rule of that framework. A more detailed discussion of this connection can be found in Section A of the Supplements, which also reviews definitions generalizing the concepts of Jacobian and Hessian in a way that preserves the chain rule. The elementary building block of our procedure is a *module* as shown in Figure 2. Like for gradient backprop, the operations required for HBP can be tabulated. Table 1 provides a selection of common modules. The derivations, which again leverage the matrix differential calculus framework, can be found in Supplements B, C, and D.

3.1 Obtaining different curvature matrices

The HBP equation yields *exact* diagonal blocks $\mathcal{H}\theta^{(1)}, \dots, \mathcal{H}\theta^{(\ell)}$ of the full parameter Hessian. They can be of interest in their own right for analysis of the loss function, but are not generally suitable for second-order optimization in the sense of (1), as they need

Table 1: Hessian backpropagation for common modules used in feedforward networks. I denotes the identity matrix. We assign matrices to upper-case (W, X, \dots) and tensors to upper-case sans serif symbols ($\mathbb{W}, \mathbb{X}, \dots$).

OPERATION	FORWARD	HBP (Equation (7))
Matrix-vector multiplication	$z(x, W) = Wx$	$\mathcal{H}x = W^\top (\mathcal{H}z)W$, $\mathcal{H}W = x \otimes x^\top \otimes \mathcal{H}z$
Matrix-matrix multiplication	$Z(X, W) = WX$	$\mathcal{H}X = (I \otimes W)^\top \mathcal{H}Z(I \otimes W)$, $\mathcal{H}W = (X^\top \otimes I)^\top \mathcal{H}Z(X^\top \otimes I)$
Addition	$z(x, b) = x + b$	$\mathcal{H}x = \mathcal{H}b = \mathcal{H}z$
Elementwise activation	$z(x) = \phi(x)$, $z_i(x) = \phi(x_i)$	$\mathcal{H}x = \text{diag}[\phi'(x)]\mathcal{H}z \text{diag}[\phi'(x)] + \text{diag}[\phi''(x) \odot \delta z]$
Skip-connection	$z(x, \theta) = x + y(x, \theta)$	$\mathcal{H}x = [I + \text{D}y(x)]^\top \mathcal{H}z[I + \text{D}y(x)] + \sum_k [\mathbb{H}y_k(x)]\delta z_k$, $\mathcal{H}\theta = [\text{D}y(\theta)]^\top \mathcal{H}z[\text{D}y(\theta)] + \sum_k [\mathbb{H}y_k(\theta)]\delta z_k$
Reshape/view	$Z(\mathbb{X}) = \text{reshape}(\mathbb{X})$	$\mathcal{H}Z = \mathcal{H}\mathbb{X}$
Index select/map π	$z(x) = \Pi x$, $\Pi_{j, \pi(j)} = 1$,	$\mathcal{H}x = \Pi^\top (\mathcal{H}z)\Pi$
Convolution	$Z(\mathbb{X}, \mathbb{W}) = \mathbb{X} \star \mathbb{W}$, $Z(W, [\mathbb{X}]) = W[\mathbb{X}]$,	$\mathcal{H}[\mathbb{X}] = (I \otimes W)\mathcal{H}Z(I \otimes W)$ $\mathcal{H}W = ([\mathbb{X}]^\top \otimes I)^\top \mathcal{H}Z([\mathbb{X}]^\top \otimes I)$
Square loss	$E(x, y) = (y - x)^\top (y - x)$	$\mathcal{H}x = 2I$
Softmax cross-entropy	$E(x, y) = -y^\top \log [p(x)]$	$\mathcal{H}x = \text{diag} [p(x)] - p(x)p(x)^\top$

neither be PSD nor invertible. For application in optimization, HBP can be modified to yield semi-definite BDAs of the Hessian. Equation (7) again provides the foundation for this adaptation, which is closely related to the concepts of KFRA (Botev et al., 2017), BDA-PCH (Chen et al., 2018), and, under certain conditions, KFAC (Martens and Grosse, 2015). We draw their connections by briefly reviewing them here.

Generalized Gauss-Newton matrix: The GGN emerges as the curvature matrix in the quadratic expansion of the loss function $E(z^{(\ell)})$ in terms of the network output $z^{(\ell)}$. It is also obtained by linearizing the network output $z^{(\ell)}(\theta, x)$ in θ before computing the loss Hessian (Martens, 2014), and reads

$$G(\theta) = \frac{1}{|Q|} \sum_{(x,y) \in Q} \left[\text{D}z^{(\ell)}(\theta) \right]^\top \text{HE}(z^{(\ell)}) \left[\text{D}z^{(\ell)}(\theta) \right].$$

To obtain diagonal blocks $G(\theta^{(i)})$, the Jacobian can be unrolled by means of the chain rule for Jacobians (Supplements, Theorem A.1) as $\text{D}z^{(\ell)}(\theta^{(i)}) = [\text{D}z^{(\ell)}(z^{(\ell-1)})] [\text{D}z^{(\ell-1)}(\theta^{(i)})] \dots$. Continued expansion shows that the Hessian $\text{HE}(z^{(\ell)})$ of the loss function with respect to the network output is propagated back through a layer by multiplication from left and right with its Jacobian. This is accomplished in HBP by *ignoring second-order effects introduced by modules*, that is by setting the Hessian of the module function to zero, therefore neglecting the second term in Equation (7). In fact, if all activations in the network are piecewise linear (e.g. ReLUs), the GGN and Hessian blocks are equivalent. Moreover, diagonal blocks of the

GGN are PSD if the loss function is convex (and thus $\text{HE}(z^{(\ell)})$ is PSD). This is because blocks are recursively left- and right-multiplied with Jacobians, which does not alter the definiteness. Hessians of the loss functions listed in Table 1 are PSD. The resulting recursive scheme has been used by Botev et al. (2017) under the acronym KFRA to optimize convex loss functions of fully-connected neural networks with piecewise linear activation functions.

Positive-curvature Hessian: Another concept of positive semi-definite BDAs of the Hessian (that additionally considers second-order module effects) was studied in Chen et al. (2018) and named the PCH. It is obtained by modification of terms in the second summand of Equation (7) that can introduce concavity during HBP. This ensures positive semi-definiteness since the first summand is semi-definite, assuming the loss Hessian $\text{HE}(z^{(\ell)})$ with respect to the network output to be positive semi-definite. Chen et al. (2018) suggest to eliminate negative curvature of a matrix by computing the eigenvalue decomposition and either discard negative eigenvalues or cast them to their absolute value. This allows the construction of PSD curvature matrices even for non-convex loss functions. In the setting of Chen et al. (2018), the PCH can empirically outperform optimization using the GGN. In usual feedforward neural networks, the concavity is introduced by nonlinear elementwise activations, and corresponds to a diagonal matrix (Table 1). Thus, convexity can be maintained during HBP by either clipping negative values to zero (PCH-clip), or taking their magnitude in the diagonal concave term (PCH-abs).

Fisher information matrix: If the network defines a conditional probability density $r(y|z^{(\ell)})$ on the labels, maximum likelihood learning for the parameterized density $p_\theta(y|x)$ will correspond to choosing a negative log-likelihood loss function, i.e. $E(z^{(\ell)}, y) = -\log r(y|z^{(\ell)})$. Common loss functions like square and cross-entropy loss can be interpreted in this way. Natural gradient descent (Amari, 1998) uses the Fisher information matrix $F(\theta) = \mathbb{E}_{p_\theta(y|x)} [(d \log p_\theta(y|x)/d\theta) (d \log p_\theta(y|x)/d\theta)^\top]$ as a PSD curvature matrix approximating the Hessian. It can be expressed as the log-predictive density’s expected Hessian under r itself: $F_r(z^{(\ell)}) = -\mathbb{E}_{r(y|z^{(\ell)})} [H \log r(y|z^{(\ell)})]$. Assuming truly i.i.d. samples x , the log-likelihood of multiple data decomposes and results in the approximation

$$F(\theta) \approx \frac{1}{|Q|} \sum_{(x,y) \in Q} [Dz^{(\ell)}(\theta)]^\top F_r(z^{(\ell)}) [Dz^{(\ell)}(\theta)].$$

In this form, the computational scheme for BDAs of the Fisher resembles the HBP of the GGN. However, instead of propagating back the loss Hessian with respect to the network, the expected Hessian of the negative log-likelihood under the model’s predictive distribution is used. Martens and Grosse (2015) use Monte-Carlo sampling to estimate this matrix in their KFAC optimizer. Relations between the Fisher and GGN are discussed in (Pascanu and Bengio, 2013; Martens, 2014); for square and cross-entropy loss, they are equivalent.

3.2 Batch learning approximations

In our HBP framework, exact multiplication by the block of the curvature matrix of parameter θ in a module comes at the cost of one gradient backpropagation to this layer. The multiplication is recursively defined in terms of multiplication by the layer output Hessian $\mathcal{H}z$. If it were possible to have an explicit representation of this matrix in memory, the recursive computations hidden in $\mathcal{H}z$ could be saved during the solution of the linear system implied by Equation (1). Unfortunately, the size of the backpropagated exact matrices scales quadratically in both the batch size³ and the number of layer’s output features. However, instead of propagating back the exact Hessian, a batch-averaged version can be used instead to circumvent the batch size scaling (originating from Botev et al. (2017)). In combination with structural information about the parameter Hessian, this strategy is used in Botev et al. (2017); Chen et al. (2018) to further approximate curvature multiplications, using quantities computed in a

single backward pass and then kept in memory for application of the matrix-vector product. We can embed these explicit schemes into our modular approach. To do so, we denote averages over a batch B by a bar, for instance $1/|B| \sum_{(x,y) \in B} HE(\theta) = \overline{HE(\theta)}$. The modified backward pass of curvature information during HBP for a module receives a batch average of the Hessian with respect to the output, $\overline{\mathcal{H}z}$, which is used to formulate the matrix-vector product with the batch-averaged parameter Hessian $\overline{\mathcal{H}\theta}$. An average of the Hessian with respect to the module input, $\overline{\mathcal{H}x}$, is passed back. Existing work (Botev et al., 2017; Chen et al., 2018) differs primarily in the specifics of how this batch average is computed. In HBP, these approximations can be formulated compactly within Equation (7). Relations to the cited works are discussed in more detail in the Supplements B.4. The approximations amounting to relations used by Botev et al. (2017) read

$$\overline{\mathcal{H}x} \approx \overline{[Dz(x)]^\top \mathcal{H}z [Dz(x)]} + \sum_k \overline{[\mathcal{H}z_k(x)] \delta z_k}, \quad (8)$$

and likewise for θ . In case of a linear layer $z(x) = Wx + b$, this approximation implies the relations $\overline{\mathcal{H}W} = x \otimes x^\top \otimes \overline{\mathcal{H}z}$, $\overline{\mathcal{H}b} = \overline{\mathcal{H}z}$, and $\overline{\mathcal{H}x} = W^\top (\overline{\mathcal{H}z}) W$. Multiplication by this weight Hessian approximation with a vector v is achieved by storing $x \otimes x^\top$, $\overline{\mathcal{H}z}$ and performing the required contractions $v \mapsto (x \otimes x^\top \otimes \overline{\mathcal{H}z})v$. Note that this approach is not restricted to curvature matrix-vector multiplication routines only. Kronecker structure in the approximation gives rise to optimization methods relying on direct inversion.

A cheaper approximation, used in Chen et al. (2018),

$$\overline{\mathcal{H}x} \approx \overline{[Dz(x)]^\top \mathcal{H}z [Dz(x)]} + \sum_k \overline{[\mathcal{H}z_k(x)] \delta z_k}, \quad (9)$$

leads to the modified relation $\overline{\mathcal{H}W} = \overline{x} \otimes \overline{x}^\top \otimes \overline{\mathcal{H}z}$ for a linear layer. As this approximation is of the same rank as $\overline{\mathcal{H}z}$, which is typically small, CG requires only a few iterations during optimization. It avoids large memory requirements for layers with numerous inputs, since it requires \overline{x} be stored instead of $x \otimes x^\top$.

Transformations that are linear in the module parameters (e.g. linear and convolutional layers), possess constant Jacobians with respect to the module input for each sample (see Table 1). Hence, in a network consisting of only these layers, both Equation (8) and (9) yield the same backpropagated Hessians $\overline{\mathcal{H}x}$. This still leaves the degree of freedom for choosing the approximation scheme in the analogous equations for θ .

Remark: Both strategies for obtaining curvature matrix BDAs (implicit exact matrix-vector multiplications and explicit propagation of approximated curvature)

³ If samples are processed independently in every module, these matrices have block structure and scale linearly in batch size. Quadratic scaling is caused by transformations across different samples, like batch normalization.

are compatible. Regarding the connection to cited works, we note that the maximally modular structure of our framework changes the nature of these approximations and allows a more flexible formulation.

4 Experiments & Implementation

We illustrate the usefulness of incorporating curvature information with the two outlined strategies by experiments with a fully-connected and a convolutional neural network (CNN) on the CIFAR-10 dataset (Krizhevsky, 2009). Following the guidelines of Schneider et al. (2019), the training loss is estimated on a random subset of the training set of equal size as the test set. Each experiment is performed for 10 different random seeds and we show the mean values with shaded intervals of one standard deviation. For the loss function we use cross-entropy. Details on the model architectures and hyperparameters are given in Supplements E.

Training procedure and update rule: In comparison to a first-order optimization procedure, the training loop with HBP has to be extended by a single backward pass to backpropagate the batch-averaged or exact loss Hessian. This yields matrix-vector products with a curvature estimate $C^{(i)}$ for each parameter block $\theta^{(i)}$ of the network. Parameter updates $\Delta\theta^{(i)}$ are obtained by applying CG to solve the linear system⁴

$$\left[\alpha I + (1 - \alpha)C^{(i)}\right] \Delta\theta^{(i)} = -\delta\theta^{(i)}, \quad (10)$$

where α acts as a step size limitation to improve robustness against noise. The CG routine terminates if the ratio of the residual norm and the gradient norm falls below a certain threshold or the maximum number of iterations has been reached. The solution returned by CG is scaled by a learning rate γ , and parameters are updated by the relation $\theta^{(i)} \leftarrow \theta^{(i)} + \gamma\Delta\theta^{(i)}$.

Fully-connected network, batch approximations, and sub-blocking: The flexibility of HBP is illustrated by extending the results in Chen et al. (2018). Investigations are performed on a fully-connected network with sigmoid activations. Solid lines in Figure 4 show the performance of the Newton-style optimizer and momentum SGD in terms of the training loss and test accuracy. The second-order method is capable to escape the initial plateau in fewer iterations.

The modularity of HBP allows for additional parallelism by splitting the linear system (10) into smaller sub-blocks, which then also need fewer iterations of CG. Doing so only requires a minor modification of the

⁴We use the same update rule as Chen et al. (2018) since we extend some of the results shown within this work.

Figure 4: SGD and different Newton-style optimizers based on the PCH-abs with batch approximations. The same fully-connected neural network of (Chen et al., 2018) was used to generate the solid baseline results. Our modular approach allows further splitting the parameter blocks into sub-blocks that can independently be optimized in parallel (dashed lines).

parameter Hessian computation by (7). Consequently, we split weights and bias terms row-wise into a specified number of sub-blocks. Performance curves are shown in Figure 4. In the initial phase, the BDA can be split into a larger number of sub-blocks without suffering from a loss in performance. The reduced curvature information is still sufficient to escape the initial plateau. However, larger blocks have to be considered in later stages to further reduce the loss efficiently.

The fact that this switch in modularity is necessary is an argument in favor of the flexible form of HBP, which allows to efficiently realize such switches: For this experiment, the splitting for each block was artificially chosen to illustrate this flexibility. In principle, the splitting could be decided individually for each parameter block, and even changed at run time.

Convolutional neural network, matrix-free exact curvature multiplication: For convolutions, the large number of hidden features prohibits backpropagating a curvature matrix batch average. Instead, we use exact curvature matrix-vector products provided within HBP. The CNN possesses sigmoid activations and cannot be trained by SGD (cf. Figure 5a). For comparison with another second-order method, we experiment with a public KFAC implementation (Martens and Grosse, 2015; Grosse and Martens, 2016, see Supplements E for details).

Figure 5: (a) Comparison of SGD, Adam, KFAC, and Newton-style methods with different exact curvature matrix-vector products (HBP) on a CNN with sigmoid activations (see Supplements E). SGD cannot train the net. (b) Wall-clock time comparison (on an RTX 2080 Ti GPU; same colors realize different random seeds).

The matrix-free second-order methods progress fast in the initial stage of the optimization. However, progress in later phases stagnates. This may be caused by the limited sophistication of the update rule (10): If a small value for α is chosen, the optimizer will perform well in the beginning (GGN, α_1). As the gradients become smaller, and hence more noisy, the step size limitation is too optimistic, which leads to a slow-down in optimization progress. A more conservative step size limitation improves the overall performance at the cost of fewer initial progress (GGN, α_2). In the training phase where damping is “effective”, our illustrative methods, and KFAC, exhibit better progress per iteration on the objective than the first-order competitor Adam, underlining the usefulness of curvature even if only computed block-wise.

For an impression on performance in terms of run time, Figure 5b compares the wall-clock time of one matrix-free method and the baselines. The HBP-based optimizer can compete with existing methods and offers potential for further improvements, like sub-blocking and parallelized CG. Despite the more adaptive nature of second-order methods, their full power seems to still require adaptive damping, to account for the quality of the local quadratic approximation and restrict the update if necessary. The importance of these techniques to properly adapt the Newton direction has been emphasized in previous works (Martens, 2010; Martens and Grosse, 2015; Botev et al., 2017) that aim to develop fully fletched second-order optimizers. Such adaptation, however, is beyond the scope of this text.

5 Conclusion

We have outlined a procedure to compute block-diagonal approximations of different curvature matrices for feedforward neural networks by a scheme that can be realized on top of gradient backpropagation. In contrast to other recently proposed methods, our implementation is aligned with the design of current machine learning frameworks and can flexibly compute Hessian sub-blocks to different levels of refinement. Its modular formulation facilitates closed-form analysis of Hessian diagonal blocks, and unifies previous approaches (Botev et al., 2017; Chen et al., 2018).

Within our framework we presented two strategies: (i) Obtaining exact curvature matrix-vector products that have not been accessible before by auto-differentiation (PCH), and (ii) backpropagation of further approximated matrix representations to save computations during training. As for gradient backpropagation, the Hessian backpropagation for different operations can be derived independently of the underlying graph. The extended modules can then be used as a drop-in replacement for existing modules to construct deep neural networks. Internally, backprop is extended by an additional Hessian backward pass through the graph to compute curvature information. It can be performed in parallel to, and reuse the quantities computed in, gradient backpropagation.

Acknowledgments

The authors would like to thank Frederik Kunstner, Matthias Werner, Frank Schneider, and Agustinus Kristiadi for their constructive feedback on the manuscript, and gratefully acknowledge financial support by the European Research Council through ERC StG Action 757275 / PANAMA; the DFG Cluster of Excellence “Machine Learning - New Perspectives for Science”, EXC 2064/1, project number 390727645; the German Federal Ministry of Education and Research (BMBF) through the Tübingen AI Center (FKZ: 01IS18039A); and funds from the Ministry of Science, Research and Arts of the State of Baden-Württemberg. This document provides additional information and derivations to clarify the relations of Hessian backpropagation (HBP). Section A contains a clean definition of Jacobian and Hessian matrices for multi-variate functions that are typically involved in the construction of neural networks. We introduce conventions for notation and show how the HBP Equation (7) results naturally from the chain rule for matrix derivatives (Magnus and Neudecker, 1999).

With matrix derivatives, the HBP equation for a variety of module functions can be derived elegantly. Sections B, C, and D contain the HBP derivations for all operations in Table 1. We split the considered operations into different categories to achieve a cleaner structure. Section B contains details on operations used for the construction of fully-connected neural networks (FCNNs) and skip-connections. Subsection B.4 illustrates the analytic composition of multiple modules by combining the backward passes of a nonlinear elementwise activation function and an affine transformation. This yields the recursive schemes of Botev et al. (2017) and Chen et al. (2018), the latter of which has been used in the experiment of Section 4. The analysis of the Hessian for common loss functions is provided in Section C. Operations occurring in convolutional neural networks (CNNs) are subject of Section D.

Section E provides details on model architectures, training procedures used in the experiments of Section 4, and an additional experiment on a modified test problem of the DeepOBS benchmark library (Schneider et al., 2019).

A Matrix derivatives

Index notation for higher-order derivatives of multi-variate matrix functions can become heavy (Mizutani and Dreyfus, 2008; Naumov, 2017; Chen et al., 2018; Bakker et al., 2018). We tackle this issue by embedding the presented approach in the notation of matrix differential calculus, which

1. yields notation consistent with established literature on matrix derivatives (Magnus and Neudecker, 1999) and clarifies the origin of the symbols D and H that are used extensively in the main text.
2. allows for using a multi-dimensional generalization of the chain rule.
3. lets us extract first- and second-order derivatives from differentials using the identification rules of Magnus and Neudecker (1999) without bothering to deal with index notation.

With these techniques it is easy to see how structure, like Kronecker products, appears in the derivatives.

Preliminaries & notation: The following definitions and theorems represent a collection of results from the book of Magnus and Neudecker (1999). They generalize the concept of first- and second-order derivatives to multi-variate matrix functions in terms of the Jacobian and Hessian matrix. While there exist multiple ways to arrange the partial derivatives, the presented definitions allows for a multivariate generalization of the chain rule.

We denote matrix, vector, and scalar functions by F , f , and ϕ , respectively. Matrix (vector) arguments are written as $X(x)$. Vectorization (vec) applies column-stacking, such that for matrices A, B, C of appropriate size

$$\text{vec}(ABC) = (C^\top \otimes A) \text{vec}(B). \quad (\text{S.1})$$

Whenever possible, we assign vectors to lower-case (for instance x, θ), matrices to upper-case (W, X, \dots), and tensors to upper-case sans serif symbols (W, X, \dots). \odot denotes elementwise multiplication (Hadamard product).

Remark on vectorization: The generalization of Jacobians and Hessians provided by Magnus and Neudecker (1999) relies on vectorization of matrices. Convolutional neural networks usually act on tensors and we incorporate these by assuming them to be flattened such that the first index varies fastest. For a matrix (tensor of order two), this is consistent with column-stacking. For instance, the vectorized version of the tensor $\mathbf{A} \in \mathbb{R}^{n_1 \times n_2 \times n_3}$ with $n_1, n_2, n_3 \in \mathbb{N}$ is $\text{vec } \mathbf{A} = (\mathbf{A}_{1,1,1}, \mathbf{A}_{2,1,1}, \dots, \mathbf{A}_{n_1,1,1}, \mathbf{A}_{1,2,1}, \dots, \mathbf{A}_{n_1,n_2,n_3})^\top$. To formulate the generalized Jacobian or Hessian for tensor operations, its action on a vector or matrix view of the original tensor is considered. Consequently, all operations can be reduced to vector-valued functions, which we consider in the following.

The vectorization scheme is not unique. Most of the linear algebra literature assumes column-stacking. However, when it comes to implementations, a lot of programming languages store tensors in row-major order, corresponding to row-stacking vectorization (last index varies fastest). Thus, special attention has to be paid in implementations.

A.1 Definitions

Definition A.1 (Jacobian matrix). Let $F : \mathbb{R}^{n \times q} \rightarrow \mathbb{R}^{m \times p}$, $X \mapsto F(X)$ be a differentiable function mapping between two matrix-sized quantities. The *Jacobian* $DF(X)$ of F with respect to X is an $(mp \times nq)$ matrix

$$DF(X) = \frac{\partial \text{vec } F(X)}{\partial (\text{vec } X)^\top}, \quad \text{such that} \quad [DF(X)]_{i,j} = \frac{\partial [\text{vec } F(X)]_i}{\partial [(\text{vec } X)^\top]_j} \quad (\text{S.2})$$

(Magnus and Neudecker, 1999, Chapter 9.4).

In the context of FCNNs, the most common occurrences of Definition A.1 involve vector-to-vector functions $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$, $x \mapsto f(x)$ with

$$Df(x) = \frac{\partial f(x)}{\partial x^\top}.$$

For instance, x can be considered the input or bias vector of a layer applying an affine transformation. Other cases involve matrix-to-vector mappings $f : \mathbb{R}^{n \times q} \rightarrow \mathbb{R}^m$, $X \mapsto f(X)$ with

$$Df(X) = \frac{\partial f(X)}{\partial (\text{vec } X)^\top},$$

where X might correspond to the $\mathbb{R}^{m \times q}$ weight matrix of an affine transformation.

Proper arrangement of the partial derivatives leads to a generalized formulation of the chain rule.

Theorem A.1 (Chain rule for Jacobians). Let $F : \mathbb{R}^{n \times q} \rightarrow \mathbb{R}^{m \times p}$ and $G : \mathbb{R}^{m \times p} \rightarrow \mathbb{R}^{r \times s}$ be differentiable matrix-to-matrix mappings and their composition H be given by $H = G \circ F : \mathbb{R}^{n \times q} \rightarrow \mathbb{R}^{r \times s}$, then

$$DH(X) = [DG(F)] DF(X) \quad (\text{S.3})$$

(restricted from Magnus and Neudecker, 1999, Chapter 5.15).

Theorem A.1 is used to unroll the Jacobians in the composite structure of the feedforward neural network's loss function $E \circ f^{(\ell)} \circ f^{(\ell-1)} \circ \dots \circ f^{(1)}$, compare Subsection 3.1.

Definition A.2 (Hessian). Let $F : \mathbb{R}^{n \times q} \rightarrow \mathbb{R}^{m \times p}$ be a twice differentiable matrix function. The *Hessian* $HF(X)$ is an $(mnpq \times nq)$ matrix defined by

$$HF(X) = D [DF(X)]^\top = \frac{\partial}{\partial (\text{vec } X)^\top} \text{vec} \left\{ \left[\frac{\partial \text{vec } F(X)}{\partial (\text{vec } X)^\top} \right]^\top \right\} \quad (\text{S.4})$$

(Magnus and Neudecker, 1999, Chapter 10.2).

Forms of Equation (S.4) that are most likely to emerge in neural networks include

$$\mathbf{H}\phi(x) = \frac{\partial^2 \phi(x)}{\partial x^\top \partial x} \quad \text{and} \quad \mathbf{H}\phi(X) = \frac{\partial}{\partial (\text{vec } X)^\top} \frac{\partial \phi(X)}{\partial \text{vec } X}.$$

The scalar function ϕ can be considered as the loss function E . Analogously, the Hessian matrix of a vector-in-vector-out function f reads

$$\mathbf{H}f(x) = \begin{pmatrix} \mathbf{H}f_1(x) \\ \vdots \\ \mathbf{H}f_m(x) \end{pmatrix}. \quad (\text{S.5})$$

Arranging the partial second derivatives in the fashion of Definition A.2 yields a direct generalization of the chain rule for second derivatives. We now provide this rule for a composition of vector-to-vector functions.

Theorem A.2 (Chain rule for Hessian matrices). Let $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ and $g : \mathbb{R}^m \rightarrow \mathbb{R}^p$ be twice differentiable and $h = g \circ f : \mathbb{R}^n \rightarrow \mathbb{R}^p$. The relation between the Hessian of h and the Jacobians and Hessians of the constituents f and g is given by

$$\mathbf{H}h(x) = [I_p \otimes \mathbf{D}f(x)]^\top [\mathbf{H}g(f)] \mathbf{D}f(x) + [\mathbf{D}g(f) \otimes I_n] \mathbf{H}f(x) \quad (\text{S.6})$$

(restricted from Magnus and Neudecker, 1999, Chapter 6.10).

A.2 Relation to the modular approach

Theorem A.2 can directly be applied to the graph $E \circ f^{(\ell)} \circ f^{(\ell-1)} \circ \dots \circ f^{(1)}$ of the feedforward net under investigation. Note that, for any module function $f^{(i)}$, the loss can be expressed as a composition of two functions by squashing preceding modules in the graph into a single function $f^{(i-1)} \circ \dots \circ f^{(1)}$, and likewise composing the module itself and all subsequent functions, i.e. $E \circ f^{(\ell)} \circ \dots \circ f^{(i)}$.

The analysis can therefore be reduced to the module shown in Figure 2 receiving an input $x \in \mathbb{R}^n$ that is used to compute the output $z \in \mathbb{R}^m$. The scalar loss is then expressed as a mapping $E(z(x), y) : \mathbb{R}^n \rightarrow \mathbb{R}^p$ with $p = 1$. Suppressing the label y , Equation (S.6) implies

$$\begin{aligned} \mathbf{H}E(x) &= [I_p \otimes \mathbf{D}z(x)]^\top [\mathbf{H}E(z)] \mathbf{D}z(x) + [\mathbf{D}E(z) \otimes I_n] \mathbf{H}z(x) \\ &= [\mathbf{D}z(x)]^\top [\mathbf{H}E(z)] \mathbf{D}z(x) + [\mathbf{D}E(z) \otimes I_n] \mathbf{H}z(x). \end{aligned} \quad (\text{S.7})$$

The HBP Equation (7) is obtained by substituting (S.5) into (S.7).

B HBP for fully-connected neural networks

B.1 Linear layer (matrix-vector multiplication, matrix-matrix multiplication, addition)

Consider the function f of a module applying an affine transformation to a vector. Apart from the input x , additional parameters of the module are given by the weight matrix W and the bias term b ,

$$\begin{aligned} f : \quad \mathbb{R}^n \times \mathbb{R}^{m \times n} \times \mathbb{R}^m &\rightarrow \mathbb{R}^m \\ (x, W, b) &\mapsto z = Wx + b. \end{aligned}$$

To compute the Jacobians with respect to each variable, we use the differentials

$$\begin{aligned} dz(x) &= W dx, \\ dz(b) &= db, \\ dz(W) &= (dW)x \implies d \text{vec } z(W) = (x^\top \otimes I_m) \text{vec}(dW), \end{aligned}$$

using Property (S.1) to establish the implication in the last line. With the *first identification tables* provided in Magnus and Neudecker (1999, Chapter 9.6), the Jacobians can be read off from the differentials as $\mathbf{D}z(x) =$

$W, Dz(b) = I_m, Dz(W) = x^\top \otimes I_m$. All second module derivatives $Hx(x)$, $Hx(W)$, and $Hx(b)$ vanish since f is linear in all inputs. Inserting the Jacobians into Equation (7) results in

$$\mathcal{H}x = W^\top \mathcal{H}zW, \quad (\text{S.8a})$$

$$\mathcal{H}b = \mathcal{H}z, \quad (\text{S.8b})$$

$$\mathcal{H}W = (x^\top \otimes I_m)^\top \mathcal{H}z (x^\top \otimes I_m) = xx^\top \otimes \mathcal{H}z = x \otimes x^\top \otimes \mathcal{H}z. \quad (\text{S.8c})$$

The HBP relations for matrix-vector multiplication and addition listed in Table 1 are special cases of Equation (S.8). HBP for matrix-matrix multiplication is derived in a completely analogous fashion.

B.2 Elementwise activation

Next, consider the elementwise application of a nonlinear function,

$$\begin{aligned} \phi: \mathbb{R}^m &\rightarrow \mathbb{R}^m \\ x \mapsto z = \phi(x) &\text{ such that } \phi_k(x) = \phi(x_k), \end{aligned}$$

For the matrix differential with respect to x , this implies

$$d\phi(x) = \phi'(x) \odot dx = \text{diag}[\phi'(x)] dx,$$

and consequently, the Jacobian is given by $D\phi(x) = \text{diag}[\phi'(x)]$. For the Hessian, note that the function value $\phi_k(x)$ only depends on x_k and thus $H\phi_k(x) = \phi''(x_k)e_k e_k^\top$, with the one-hot unit vector $e_k \in \mathbb{R}^m$ in coordinate direction k . Inserting all quantities into the Relation (7) results in

$$\begin{aligned} \mathcal{H}x &= \text{diag}[\phi'(x)] \mathcal{H}z \text{diag}[\phi'(x)] + \sum_k \phi''(x_k) e_k e_k^\top \delta z_k \\ &= \text{diag}[\phi'(x)] \mathcal{H}z \text{diag}[\phi'(x)] + \text{diag}[\phi''(x) \odot \delta z]. \end{aligned} \quad (\text{S.9})$$

B.3 Skip-connection

Residual learning He et al. (2016) uses skip-connection units to facilitate the training of deep neural networks. In its simplest form, the mapping $f: \mathbb{R}^m \rightarrow \mathbb{R}^m$ reads

$$z(x, \theta) = x + y(x, \theta),$$

with a potentially nonlinear operation $(x, \theta) \mapsto y$. The Jacobians with respect to the input and parameters are given by $Dz(x) = I_m + Dy(x)$ and $Dz(\theta) = Dy(\theta)$. Using (7), one finds

$$\begin{aligned} \mathcal{H}x &= [I_m + Dy(x)]^\top \mathcal{H}z [I_m + Dy(x)] + \sum_k [Hy_k(x)] \delta z_k, \\ \mathcal{H}\theta &= [Dy(\theta)]^\top \mathcal{H}z [Dy(\theta)] + \sum_k [Hy_k(\theta)] \delta z_k. \end{aligned}$$

B.4 Relation to recursive schemes in previous work

The modular decomposition of curvature backpropagation facilitates the analysis of modules composed of multiple operations. Now, we analyze the composition of two modules. This yields the recursive schemes presented by Botev et al. (2017) and Chen et al. (2018), referred to as KFRA and BDA-PCH, respectively.

B.4.1 Analytic composition of multiple modules

Consider the module $g = f \circ \phi, x \mapsto y = \phi(x), y \mapsto z = f(y(x))$. We assume ϕ to act elementwise on the input, followed by a linear layer $f: z(y) = Wy + b$ (Figure S.1a). Analytic elimination of the intermediate backward pass yields a single module composed of two operations (Figure S.1b).

Figure S.1: Composition of elementwise activation ϕ and linear layer. (a) Both operations are analyzed separately to derive the HBP. (b) Backpropagation of $\mathcal{H}z$ is expressed in terms of $\mathcal{H}x$ without intermediate message.

The first Hessian backward pass through the linear module f (Equations (S.8)) implies

$$\mathcal{H}y = W^\top \mathcal{H}z W, \quad (\text{S.10a})$$

$$\mathcal{H}W = y \otimes y^\top \otimes \mathcal{H}z = \phi(x) \otimes \phi(x)^\top \otimes \mathcal{H}z, \quad (\text{S.10a})$$

$$\mathcal{H}b = \mathcal{H}z. \quad (\text{S.10b})$$

Further backpropagation through ϕ by means of Equation (S.9) results in

$$\begin{aligned} \mathcal{H}x &= \text{diag}[\phi'(x)] \mathcal{H}y \text{diag}[\phi'(x)] + \text{diag}[\phi''(x) \odot \delta y] \\ &= \text{diag}[\phi'(x)] [W^\top \mathcal{H}z W] \text{diag}[\phi'(x)] + \text{diag}[\phi''(x) \odot W^\top \delta z] \\ &= \{W \text{diag}[\phi'(x)]\}^\top \mathcal{H}z \{W \text{diag}[\phi'(x)]\} + \text{diag}[\phi''(x) \odot W^\top \delta z]. \end{aligned} \quad (\text{S.10c})$$

We use the invariance of a diagonal matrix under transposition and $\delta y = W^\top \delta z$ for the backpropagated gradient to establish the last equality. The Jacobian $Dg(x)$ of the module shown in Figure S.1b is $Dg(x) = W \text{diag}[\phi(x)] = [W^\top \odot \phi'(x)]^\top$. In summary, the HBP relation for the composite layer $z(x) = W\phi(x) + b$ is given by (S.10).

B.4.2 Obtaining the relations of KFRA and BDA-PCH

The derivations for the composite module given above are closely related to the recursive schemes of Botev et al. (2017); Chen et al. (2018). Their relations are obtained from a straightforward conversion of the HBP rules (S.10). Consider a sequence of a linear layer $f^{(1)}$ and multiple composite modules $f^{(2)}, \dots, f^{(\ell)}$ as shown in Figure S.2.

According to Equation (S.10b) both the linear layer and the composite $f^{(i)}$ identify the gradient (Hessian) with respect to their outputs, $\delta z^{(i)}$ ($\mathcal{H}z^{(i)}$), as the gradient (Hessian) with respect to their bias term, $\delta b^{(i)}$ ($\mathcal{H}b^{(i)}$). Introducing layer indices for all quantities, one finds the recursion

$$\mathcal{H}b^{(i)} = \mathcal{H}z^{(i)}, \quad (\text{S.11a})$$

$$\mathcal{H}W^{(i)} = \phi(z^{(i-1)}) \otimes \phi(z^{(i-1)})^\top \otimes \mathcal{H}b^{(i)}, \quad (\text{S.11b})$$

for $i = \ell - 1, \dots, 1$, and

$$\begin{aligned} \mathcal{H}z^{(i-1)} &= \left\{ W^{(i)} \text{diag}[\phi'(z^{(i-1)})] \right\}^\top \mathcal{H}b^{(i)} \left\{ W^{(i)} \text{diag}[\phi'(z^{(i-1)})] \right\} + \text{diag}[\phi''(z^{(i-1)}) \odot W^{(i)\top} \delta b^{(i)}] \\ &= \left\{ W^{(i)\top} \odot \phi'(z^{(i-1)}) \right\} \mathcal{H}b^{(i)} \left\{ W^{(i)\top} \odot \phi'(z^{(i-1)}) \right\}^\top + \text{diag}[\phi''(z^{(i-1)}) \odot W^{(i)\top} \delta b^{(i)}] \end{aligned} \quad (\text{S.11c})$$

for $i = \ell - 1, \dots, 2$. It is initialized with the gradient $\delta z^{(\ell)}$ and Hessian $\mathcal{H}z^{(\ell)}$ of the loss function.

Equations (S.11) are equivalent to the expressions provided in Botev et al. (2017); Chen et al. (2018). Their emergence from compositions of HBP equations of simple operations represents one key insight of this paper. Both works use the batch average strategy presented in Subsection 3.2 to obtain curvature estimates.

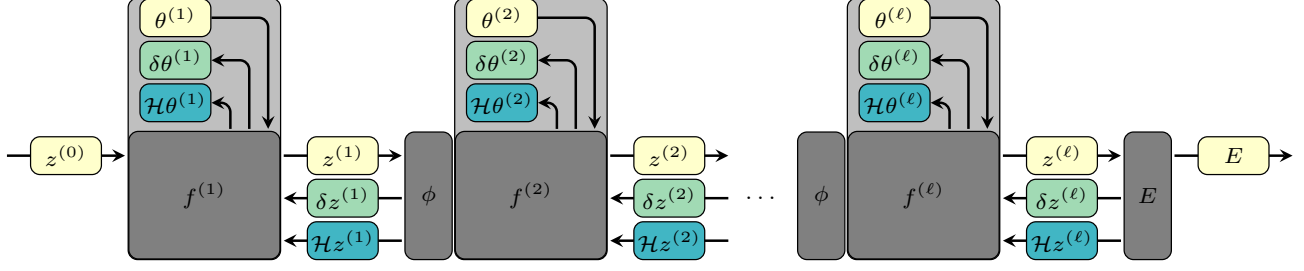

Figure S.2: Grouping scheme for the recursive Hessian computation proposed by KFRA and BDA-PCH. The backward messages between the linear layer and the preceding nonlinear activation are analytically absorbed.

C HBP for loss functions

C.1 Square loss

Square loss of the model prediction $x \in \mathbb{R}^m$ and the true label $y \in \mathbb{R}^m$ is computed by

$$E(x, y) = (y - x)^\top (y - x).$$

Differentiating $dE(x) = -(dx)^\top (y - x) - (y - x)^\top dx = -2(y - x)^\top dx$ once more yields

$$d^2E(x) = 2(dx)^\top dx = 2(dx)^\top I_m dx.$$

The Hessian is extracted with the *second identification tables* from Magnus and Neudecker (1999, Chapter 10.4) and reproduces the expected result

$$HE(x) = \mathcal{H}x = 2I_m. \quad (\text{S.12})$$

C.2 Softmax cross-entropy loss

The computation of cross-entropy from logits is composed of two operations. First, the neural network outputs are transformed into log-probabilities by the softmax function. Then, the cross-entropy with the label is computed.

Log-softmax: The output's elements $x \in \mathbb{R}^m$ of a neural network are assigned to log-probabilities $z(x) = \log[p(x)] \in \mathbb{R}^m$ by means of the softmax function $p(x) = \exp(x)/\sum_i \exp(x_i)$. Consequently,

$$z(x) = x - \log \left[\sum_i \exp(x_i) \right],$$

and the Jacobian reads $Dz(x) = I_m - p(x)\mathbf{1}_m^\top$ with $\mathbf{1}_m^\top \in \mathbb{R}^m$ denoting a vector of ones. Moreover, the log-probability Hessians with respect to x are given by $\mathcal{H}z_k(x) = -\text{diag}[p(x)] + p(x)p(x)^\top$.

Cross-entropy: The negative log-probabilities are used to compute the cross-entropy with the probability distribution of the label $y \in \mathbb{R}^m$ with $\sum_k y_k = 1$ (usually a one-hot vector),

$$E(z, y) = -y^\top z.$$

Since E is linear in the log-probabilities, that is $HE(z) = 0$, the HBP is given by

$$\begin{aligned} \mathcal{H}x &= [Dz(x)]^\top HE(z) [Dz(x)] + \sum_k \mathcal{H}z_k(x) \frac{\partial E(z)}{\partial z_k} \\ &= \{-\text{diag}[p(x)] + p(x)p(x)^\top\} \sum_k (-y_k) \\ &= \text{diag}[p(x)] - p(x)p(x)^\top. \end{aligned}$$

D HBP for convolutional neural networks

The recursive approaches presented in Botev et al. (2017); Chen et al. (2018) tackle the computation of curvature blocks for FCNNs. To the best of our knowledge, an extension to CNNs has not been achieved so far. One reason this might be is that convolutions come with heavy notation that is difficult to deal with in index notation.

Martens and Grosse (2015) provide a procedure for computing a Kronecker-factored approximation of the Fisher for convolutions (KFC). This scheme relies on the property of the Fisher to describe the covariance of the log-likelihood’s gradients under the model’s distribution. Curvature information is thus encoded in the expectation value, and not by backpropagation of second-order derivatives.

To derive the HBP for convolutions, we use the fact that an efficient implementation of the forward pass is decomposed into multiple operations (see Figure S.4), which can be considered independently by means of our modular approach (see Figure S.5 for details). Our analysis starts by considering the backpropagation of curvature through operations that occur frequently in CNNs. This includes the reshape (Subsection D.1) and extraction operation (Subsection D.2). In Subsection D.3 we outline the modular decomposition and curvature backpropagation of convolution for the two-dimensional case. The approach carries over to other dimensions.

All operations under consideration in this Section are linear. Hence the second terms in Equation (7) vanish. Again, we use the framework of matrix differential calculus (Magnus and Neudecker, 1999) to avoid index notation.

D.1 Reshape/view

The reshape operation reinterprets a tensor $\mathbf{X} \in \mathbb{R}^{n_1 \times \dots \times n_x}$ as another tensor $\mathbf{Z} \in \mathbb{Z}^{m_1 \times \dots \times m_z}$

$$\mathbf{Z}(\mathbf{X}) = \text{reshape}(\mathbf{X}),$$

which possesses the same number of elements, that is $\prod_i n_i = \prod_i m_i$. One example is given by the `vec` operation. It corresponds to a reshape into a tensor of order one. As the arrangement of elements remains unaffected, $\text{vec } \mathbf{Z} = \text{vec } \mathbf{X}$, and reshaping corresponds to the identity map on the vectorized input. Consequently, one finds (remember that $\mathcal{H}\mathbf{X}$ is a shorthand notation for $\mathcal{H} \text{vec } \mathbf{X}$)

$$\mathcal{H}\mathbf{X} = \mathcal{H}\mathbf{Z}.$$

D.2 Index select/map

Whenever elements of a tensor are selected by an operation, it can be described as a matrix-vector multiplication of a binary matrix $\mathbf{\Pi}$ and the vectorized tensor. The mapping is described by an index map π . Element j of the output $z \in \mathbb{R}^m$ is selected as element $\pi(j)$ from the input $x \in \mathbb{R}^n$. Only elements $\Pi_{j,\pi(j)}$ in the selection matrix $\mathbf{\Pi} \in \mathbb{R}^{m \times n}$ are one, while all other entries vanish. Consequently, index selection can be expressed as

$$z_j = x_{\pi(j)} \Leftrightarrow z(x) = \mathbf{\Pi}x \quad \text{with} \quad \Pi_{j,\pi(j)} = 1.$$

The HBP is equivalent to the linear layer discussed in Subsection B.1,

$$\mathcal{H}z = \mathbf{\Pi}^\top (\mathcal{H}x) \mathbf{\Pi}.$$

Applications include max-pooling and the `im2col/unfold` operation (see Subsection D.3). Average-pooling represents a weighted sum of index selections and can be treated analogously.

D.3 Convolution

The convolution operation acts on local patches of a multi-channel input of sequences, images, or volumes. In the following, we restrict the discussion to two-dimensional convolution. Figure S.3a illustrates the setting. A collection of filter maps, the *kernel* \mathbf{W} , is slid over the spatial coordinates of the input tensor \mathbf{X} . In each step, the kernel is contracted with the current area of overlap (the *patch*).

Both the sliding process as well as the structure of the patch area can be controlled by hyperparameters of the operation (kernel size, stride, dilation). Moreover, it is common practice to extend the input tensor, for instance by zero-padding (for an introduction to the arithmetics of convolutions, see Dumoulin and Visin, 2016). The approach presented here is not limited to a certain choice of convolution hyperparameters.

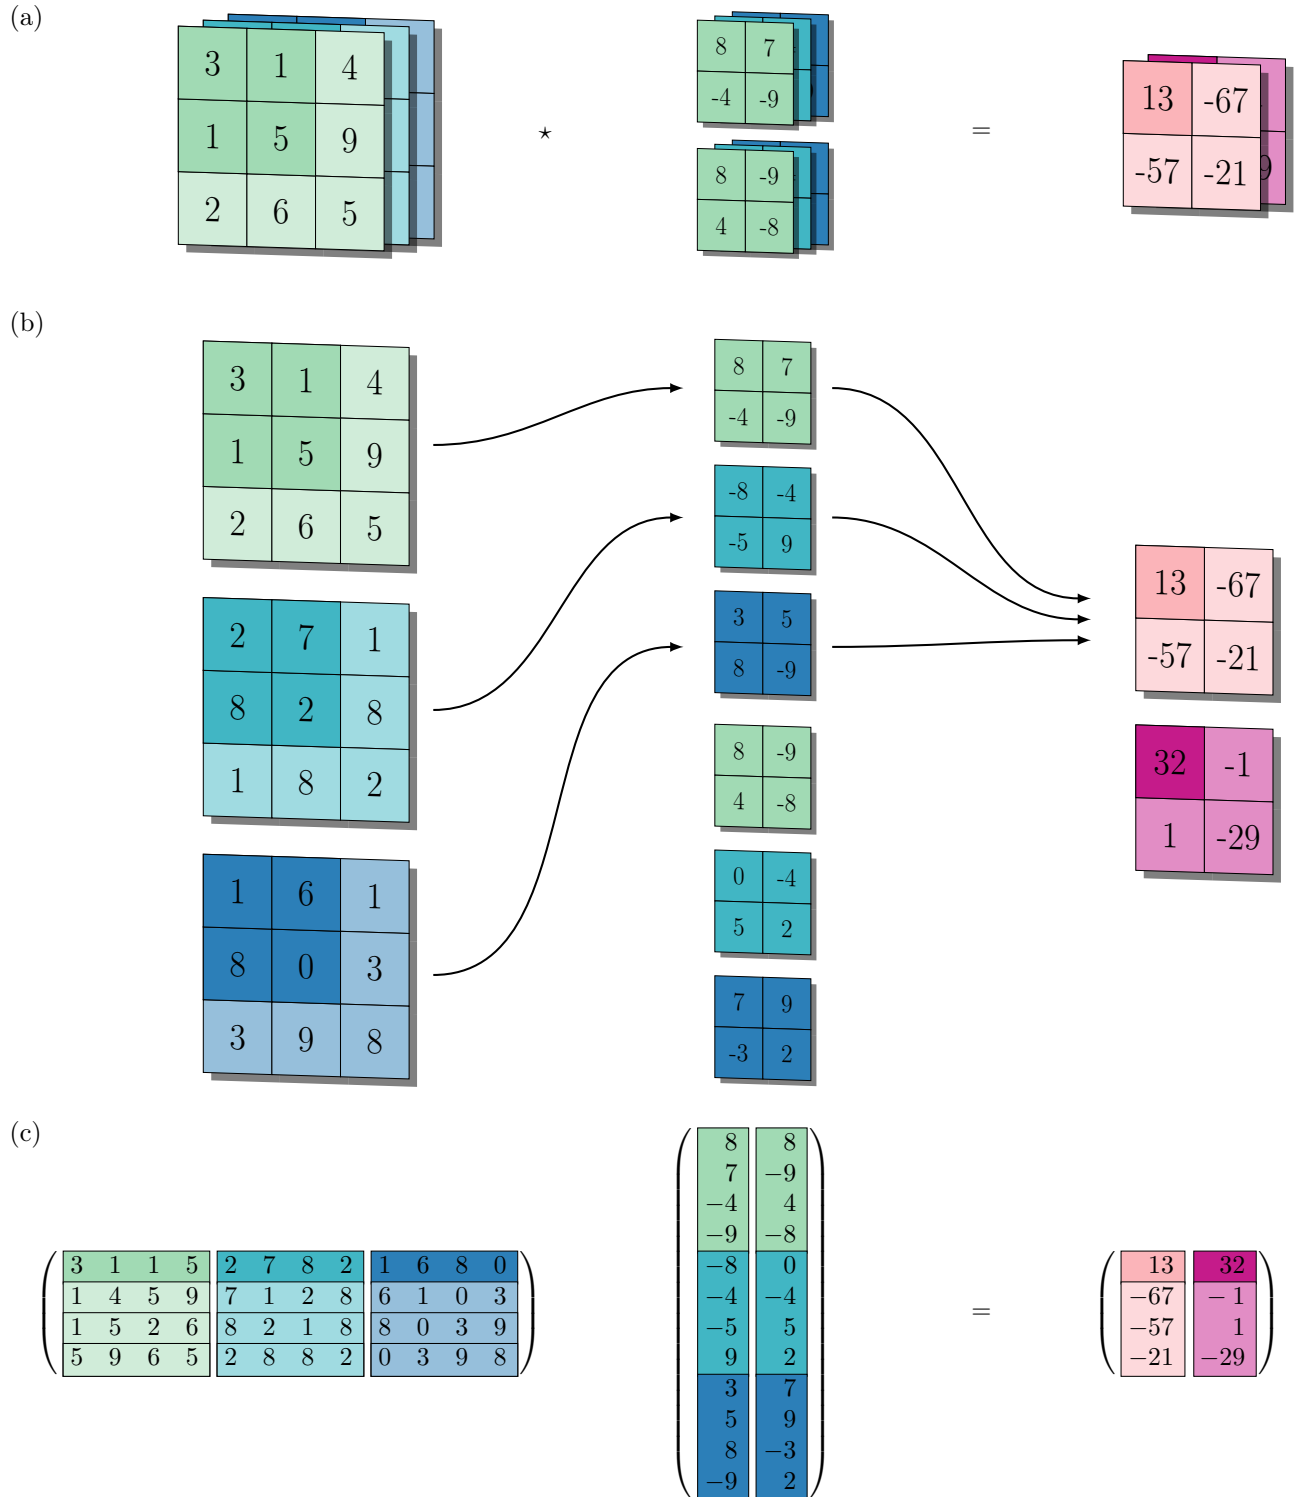

Figure S.3: Two-dimensional convolution $Y = X \star W$ without bias term. (a) The input X consists of $C_{in} = 3$ channels (different colors) of (3×3) images. Filter maps of size (2×2) are provided by the kernel W for the generation of $C_{out} = 2$ output channels. Patch and kernel volumes that are contracted in the first step of the convolution are highlighted. Assuming no padding and a stride of one results in four patches. New features Y consist of $C_{out} = 2$ channels of (2×2) images. (b) Detailed view. All tensors are unrolled along the first axis. (c) Convolution as matrix multiplication. From left to right, the matrices $\llbracket X \rrbracket^T$, W^T , and Y^T are shown.

Figure S.4: Decomposition of the convolution operation’s forward pass.

Table S.1: Important quantities for the convolution operation. The number of patches equals the product of the outputs’ spatial dimensions, i.e. $P = Y_1 Y_2$.

Tensor	Dimensionality	Description
X	$(C_{\text{in}}, X_1, X_2)$	Input
W	$(C_{\text{out}}, C_{\text{in}}, K_1, K_2)$	Kernel
Y	$(C_{\text{out}}, Y_1, Y_2)$	Output
$\llbracket X \rrbracket$	$(C_{\text{in}} K_1 K_2, P)$	Expanded input
W	$(C_{\text{out}}, C_{\text{in}} K_1 K_2)$	Matricized kernel
Y	(C_{out}, P)	Matricized output
b	C_{out}	Bias vector
B	(C_{out}, P)	Bias matrix

D.3.1 Forward pass and notation

We now introduce the quantities involved in the process along with their dimensions. For a summary, see Table S.1. A forward pass of convolution proceeds as follows (cf. Figure S.3b for an example):

- The input X , a tensor of order three, stores a collection of two-dimensional data. Its components $X_{c_{\text{in}}, x_1, x_2}$ are referenced by indices for the channel c_{in} and the spatial location (x_1, x_2) . C_{in}, X_1, X_2 denote the input channels, width, and height of the image, respectively.
- The kernel W is a tensor of order four with dimensions $(C_{\text{out}}, C_{\text{in}}, K_1, K_2)$. Kernel width K_1 and height K_2 determine the patch size $P = K_1 K_2$ for each channel. New features are obtained by contracting the patch and kernel. This is repeated for a collection of C_{out} output channels stored along the first axis of W .
- Each output channel c_{out} is shifted by a bias $b_{c_{\text{out}}}$, stored in the C_{out} -dimensional vector b .
- The output $Y = X \star W$ with components $Y_{c_{\text{out}}, y_1, y_2}$ is of the same structure as the input. We denote the spatial dimensions of Y by Y_1, Y_2 , respectively. Hence Y is of dimension $(C_{\text{out}}, Y_1, Y_2)$.

Example (index notation): A special case where input and output have the same spatial dimensions (Grosse and Martens, 2016) uses a stride of one, kernel widths $K_1 = K_2 = 2K + 1$, $(K \in \mathbb{N})$, and padding K . Elements of the filter $W_{c_{\text{out}}, c_{\text{in}}, :, :}$ are addressed with the index set $\{-K, \dots, 0, \dots, K\} \times \{-K, \dots, 0, \dots, K\}$. In this setting,

$$Y_{c_{\text{out}}, y_1, y_2} = \sum_{k_1=-K}^K \sum_{k_2=-K}^K X_{c_{\text{in}}, x_1+k_1, x_2+k_2} W_{c_{\text{out}}, c_{\text{in}}, k_1, k_2} + b_{c_{\text{out}}}. \quad (\text{S.13})$$

Elements of X addressed out of bounds evaluate to zero. Arbitrary convolutions come with even heavier notation.

Convolution by matrix multiplication: Evaluating convolutions by sums of the form (S.13) leads to poor memory locality (Grosse and Martens, 2016). For improved performance, the computation is mapped to a matrix multiplication (Chellapilla et al., 2006). To do so, patches of the input X are extracted and flattened into columns of a matrix. The patch extraction is indicated by the operator $\llbracket \cdot \rrbracket$ and the resulting matrix $\llbracket X \rrbracket$ is of dimension $(C_{\text{in}} K_1 K_2 \times P)$ (cf. left part of Figure S.3c showing $\llbracket X \rrbracket^\top$). In other words, elements contracted with the kernel are stored along the first axis of $\llbracket X \rrbracket$. $\llbracket \cdot \rrbracket$ is also referred to as im2col or unfold operation¹, and accounts for padding.

The kernel tensor W is reshaped into a $(C_{\text{out}} \times C_{\text{in}} K_1 K_2)$ matrix W , and elements of the bias vector b are copied columnwise into a $(C_{\text{out}} \times P)$ matrix $B = b \mathbf{1}_P^\top$, where $\mathbf{1}_P$ is a P -dimensional vector of ones. Patchwise contractions are carried out by matrix multiplication and yield a matrix Y of shape (C_{out}, P) with $P = Y_1 Y_2$,

$$Y = W \llbracket X \rrbracket + B \quad (\text{S.14})$$

(Figure S.3c shows the quantities W^\top , $\llbracket X \rrbracket^\top$, and Y from left to right). Reshaping Y into a $(C_{\text{out}}, Y_1, Y_2)$ tensor, referred to as col2im, yields Y . Figure S.4 summarizes the outlined decomposition of the forward pass.

¹Our definition of the unfold operator slightly differs from Grosse and Martens (2016), where flattened patches are stacked rowwise. This lets us achieve an analogous form to a linear layer. Conversion is achieved by transposition.

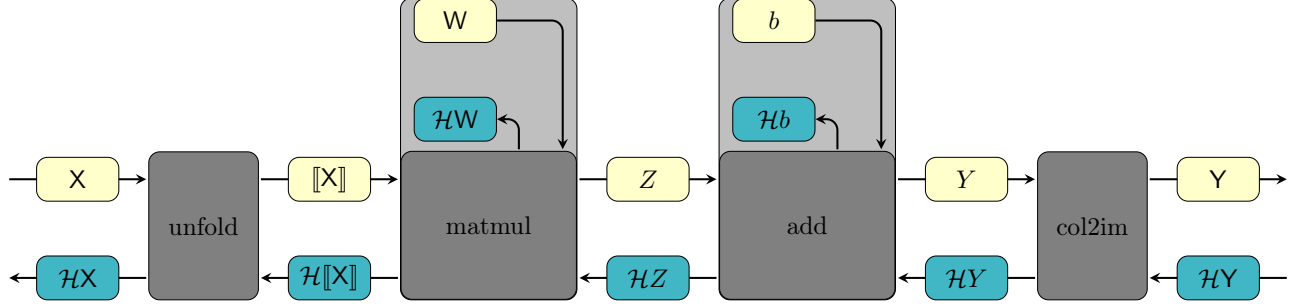

Figure S.5: Decomposition of convolution with notation for the study of curvature backpropagation.

D.4 HBP for convolution

We now compose the HBP for convolution, proceeding from right to left with the operations depicted in Figure S.5, by analyzing the backpropagation of curvature for each module, adopting the figure’s notation.

Col2im/reshape: The col2im operation takes a matrix $Y \in \mathbb{R}^{C_{\text{out}} \times Y_1 Y_2}$ and reshapes it into the tensor $\Upsilon \in \mathbb{R}^{C_{\text{out}} \times Y_1 \times Y_2}$. According to Subsection D.1, $\mathcal{H}\Upsilon = \mathcal{H}Y$.

Bias Hessian: Forward pass $Y = Z + B$ and Equation (S.8b) imply $\mathcal{H}Y = \mathcal{H}B = \mathcal{H}Z$. To obtain the Hessian with respect to b from $\mathcal{H}B$, consider the columnwise copy operation $B(b) = b \mathbf{1}_P^\top$, whose matrix differential is $dB(b) = (db) \mathbf{1}_P^\top$. Vectorization yields $d \text{vec } B(b) = (\mathbf{1}_P \otimes I_{C_{\text{out}}}) db$. Hence, the Jacobian is $DB(b) = \mathbf{1}_P \otimes I_{C_{\text{out}}}$, and insertion into Equation (7) results in

$$\mathcal{H}b = (\mathbf{1}_P \otimes I_{C_{\text{out}}})^\top \mathcal{H}B (\mathbf{1}_P \otimes I_{C_{\text{out}}}) .$$

This performs a linewise and columnwise summation over $\mathcal{H}B$, summing entities that correspond to copies of the same entry of b in the matrix B . It can also be regarded as a reshape of $\mathcal{H}B$ into a $(C_{\text{out}}, P, C_{\text{out}}, P)$ tensor, which is then contracted over the second and fourth axis.

Weight Hessian: For the matrix-matrix multiplication $Z(W, \llbracket X \rrbracket) = W \llbracket X \rrbracket$, the HBP was discussed in Subsection B.1. The Jacobians are given by $DZ(\llbracket X \rrbracket) = I_P \otimes W$ and $DZ(W) = \llbracket X \rrbracket^\top \otimes I_S$ with the patch size $S = C_{\text{in}} K_1 K_2$. Hence, the HBP for the unfolded input and the weight matrix are

$$\begin{aligned} \mathcal{H}\llbracket X \rrbracket &= (I_P \otimes W)^\top \mathcal{H}Z (I_P \otimes W) , \\ \mathcal{H}W &= (\llbracket X \rrbracket^\top \otimes I_S)^\top \mathcal{H}Z (\llbracket X \rrbracket^\top \otimes I_S) . \end{aligned}$$

From what has been said about the reshape operation in Subsection D.1, it follows that $\mathcal{H}W = \mathcal{H}W$.

Im2col/unfold: The patch extraction operation $\llbracket \cdot \rrbracket$ copies all elements in a patch into the columns of a matrix and thus represents a selection of elements by an index map, which is hard to express in notation. Numerically, it can be obtained by calling im2col on a $(C_{\text{in}}, X_1, X_2)$ index tensor whose entries correspond to the indices. The resulting tensor contains all information about the index map. HBP follows the relation of Subsection D.2.

Discussion: Although convolution can be understood as a matrix multiplication, the parameter Hessian is not identical to that of the linear layer discussed in Subsection B.1. The difference is due to the parameter sharing of the convolution. In the case of a linear layer $z = Wx + b$, the Hessian of the weight matrix for a single sample possesses Kronecker structure (Botev et al., 2017; Chen et al., 2018; Bakker et al., 2018), i.e. $\mathcal{H}W = x \otimes x^\top \otimes \mathcal{H}z$. For convolution layers, however, it has been argued by Bakker et al. (2018) that block diagonals of the Hessian do not inherit the same structure. Rephrasing the forward pass (S.14) in terms of vectorized quantities, we find

$$\text{vec } Y = (I_P \otimes W) \text{vec} \llbracket X \rrbracket + \text{vec } B .$$

In this perspective, convolution corresponds to a fully-connected linear layer, with the additional constraints that the weight and bias matrix be circular. Defining $\hat{W} = I_P \otimes W$, one then finds the Hessian $\mathcal{H}\hat{W}$ to possess Kronecker structure. Parameterization with a kernel tensor encodes the circularity constraint in weight sharing.

Table S.2: Model architectures under consideration. We use the patterns Linear(in_features, out_features), Conv2d(in_channels, out_channels, kernel_size, padding), MaxPool2d(kernel_size, stride), and ZeroPad2d(padding_left, padding_right, padding_top, padding_bottom) to describe module hyperparameters. Convolution strides are always chosen to be one. (a) FCNN used to extend the experiment in Chen et al. (2018) (3846810 parameters). (b) CNN architecture (1099226 parameters). (c) DeepOBS c3d3 test problem with three convolutional and three dense layers (895210 parameters). ReLU activation functions are replaced by sigmoids.

For the Hessian $\mathcal{H}W$ of the kernel to possess Kronecker structure, the output Hessian $\mathcal{H}Z$ has to be assumed to factorize into a Kronecker product of $S \times S$ and $C_{\text{out}} \times C_{\text{out}}$ matrices. These assumptions are somewhat in parallel with the additional approximations introduced in Grosse and Martens (2016) to obtain KFC.

E Experimental details

Fully-connected neural network: The same model as in Chen et al. (2018) (see Table S.2a) is used to extend the experiment performed therein. The weights of each linear layer are initialized with the Xavier method of Glorot and Bengio (2010). Bias terms are initialized to zero. Backpropagation of the Hessian uses approximation (9) of (S.11) to compute the curvature blocks of the weights and bias, $\overline{\mathcal{H}W^{(i)}}$ and $\overline{\mathcal{H}b^{(i)}}$.

Hyperparameters are chosen as follows to obtain consistent results with the original work: All runs shown in Figure 4 use a batch size of $|B| = 500$. For SGD, the learning rate is assigned to $\gamma = 0.1$ with momentum $v = 0.9$. Block-splitting experiments with the second-order method use the PCH-abs. All runs were performed with a learning rate $\gamma = 0.1$ and a regularization strength of $\alpha = 0.02$. For the convergence criterion of CG, the maximum number of iterations is restricted to $n_{\text{CG}} = 50$; convergence is reached at a relative tolerance $\epsilon_{\text{CG}} = 0.1$.

Convolutional neural net: The training procedure of the CNN architecture shown in Table S.2b is evaluated on a hyperparameter grid. Runs with smallest final training loss are selected to rerun on different random seeds. The curves shown in Figure 5b represent mean values and standard deviations for ten different realizations over the random seed. All layer parameters were initialized with the default method in PyTorch.

For the first-order optimizers (SGD, Adam), we considered batch sizes $B \in \{100, 200, 500\}$. In the case of SGD, momentum v was tuned over the set $\{0, 0.45, 0.9\}$. Although we varied the learning rate over a large range of values $\gamma \in \{10^{-3}, 10^{-2}, 0.1, 1, 10\}$, losses kept plateauing and did not decrease. In particular, the loss function even

Figure S.6: Comparison of SGD, Adam, and Newton-style methods with different exact curvature matrix-vector products (HBP) on the DeepOBS c3d3 network (Schneider et al., 2019) with sigmoid activations (Table S.2c).

increased for the large learning rates. For Adam, we only vary the learning rate $\gamma \in \{10^{-4}, 10^{-3}, 10^{-2}, 0.1, 1, 10\}$.

As second-order methods scale better to large batch sizes, we considered $B \in \{200, 500, 1000\}$ for them. The convergence parameters for CG were fixed to $n_{CG} = 200$ and $\epsilon_{CG} = 0.1$. For all curvature matrices, we varied the learning rates over the grid $\gamma \in \{0.05, 0.1, 0.2\}$ and $\alpha \in \{10^{-4}, 10^{-3}, 10^{-2}\}$.

In order to compare with another second-order method, we experimented with a public PyTorch implementation² of the KFAC optimizer (Martens and Grosse, 2015; Grosse and Martens, 2016). All hyperparameters were kept at their default setting. The learning rate was varied over $\gamma \in \{10^{-4}, 10^{-3}, 10^{-2}, 0.1, 1, 10\}$.

The hyperparameters of results shown in Figure 5 read as follows:

- SGD ($|B| = 100, \gamma = 10^{-3}, v = 0.9$). The particular choice of these hyperparameters is artificial. This run is representative for SGD, which does not achieve any progress at all.
- Adam ($|B| = 100, \gamma = 10^{-3}$)
- KFAC ($|B| = 500, \gamma = 0.1$)
- PCH-abs ($|B| = 1000, \gamma = 0.2, \alpha = 10^{-3}$), PCH-clip ($|B| = 1000, \gamma = 0.1, \alpha = 10^{-4}$)
- GGN, α_1 ($|B| = 1000, \gamma = 0.1, \alpha = 10^{-4}$). This run does not yield the minimum training loss on the grid, and is shown to illustrate that the second-order method is capable to escape the flat regions in early stages.
- GGN, α_2 ($|B| = 1000, \gamma = 0.1, \alpha = 10^{-3}$). In comparison with α_1 , the second-order method requires more iterations to escape the initial plateau, caused by the larger regularization strength. However, this leads to improved robustness against noise in later stages of the training procedure.

Additional experiment: Another experiment conducted with HBP considers the c3d3 architecture (Table S.2c) of DeepOBS (Schneider et al., 2019) on CIFAR-10. ReLU activations are replaced by sigmoids to make the problem more challenging. The hyperparameter grid is chosen identically to the CNN experiment above, and results are summarized in Figure S.6. In particular, the hyperparameter settings for each competitor are:

- SGD ($|B| = 100, \gamma = 1, v = 0$)
- Adam ($|B| = 100, \gamma = 10^{-3}$)
- PCH-abs ($|B| = 500, \gamma = 0.1, \alpha = 10^{-3}$), PCH-clip ($|B| = 500, \gamma = 0.1, \alpha = 10^{-2}$)
- GGN ($|B| = 500, \gamma = 0.05, \alpha = 10^{-3}$)
